Sepsis in children

Adrian Plunkett, Jeremy Tong

Sepsis is a clinical syndrome resulting from a dysregulated systemic inflammatory response to infection. It is characterised by a generalised pro-inflammatory cascade, which may lead to widespread tissue injury. It encompasses a clinical spectrum of severity, including severe sepsis, septic shock, and multi-organ failure. Sepsis is a leading cause of morbidity and mortality in children worldwide.

The aim of this review is to provide an overview of the causes, diagnosis, and current management of sepsis in children.

What is the epidemiology?

Global data on sepsis in children are incomplete, but it is estimated that infection accounts for most deaths (almost 60%) in children aged under 5 years.

The World Health Organization has stated that the four big causes of death in children worldwide are infectious diseases: pneumonia (1.9 million deaths/year), diarrhoea (1.6 million deaths/year), malaria (1.1 million deaths/year), and measles (550 000 deaths/year).

The largest epidemiological reports of the incidence of severe sepsis in children come from US cohort studies. These studies show a rising annual incidence of severe sepsis (0.56 to 0.89 cases/1000 children, across all age groups). The incidence of severe sepsis in these cohorts was significantly higher in younger age groups (incidence in the neonatal age group and infants aged <1 year was 9.7 and 2.25 cases per 1000 children, compared with 0.23 to 0.52 in children aged 1 to 19 years). Severe sepsis was also more common in children with comorbidities. Despite the rising incidence of severe sepsis, the case fatality rate has fallen from 10.3% to 8.9%.

What causes sepsis?

While any infection may precipitate sepsis, the most common pathogens are bacteria, viruses, and fungi. The type of pathogen varies according to host factors, including age, comorbidity, and geographic location. Typical or important pathogens by patient group are listed in box 1.

Sepsis occurs when the normal, pro-inflammatory host response to infection exceeds its usual homeostatic constraints and becomes a generalised process, resulting in inflammation remote from the infection source.

While this model of sepsis is intuitive, the results of emerging research suggest that it may be an oversimplification and that the pathophysiology includes processes such as endothelium dysfunction, cell death, bioenergetic derangement, and immunoparalysis.

Can sepsis be prevented?

Primary prevention

The principal method of primary prevention is immunisation. Advances in biotechnology have led to new and improved vaccines, including vaccines for Haemophilus influenzae type b, Neisseria meningitides (type C), and Streptococcus pneumoniae.

A new group B meningococcal vaccine has been licensed in Europe. In 2015, the meningococcal B vaccine will be introduced to the routine childhood vaccination programme in the UK.

Primary prevention is also relevant with healthcare associated infections. Since these infections are related to specific interventions (such as insertion of a vascular catheter), there are opportunities to reduce the risk of infection through improvements in clinical practice (such as improved handwashing practices, protective isolation, and universal precautions).

Screening

Screening for sepsis in the asymptomatic population is not useful. However, screening for maternal colonisation with group B streptococci in pregnancy has been shown in some settings to reduce the burden of group B streptococci disease in newborns.

Secondary prevention

Long term antimicrobial prophylaxis with antibiotics, antivirals, or antifungals is recommended in immunocompromised patients with premorbid conditions (such as leukaemia). Children with cystic fibrosis and other respiratory diseases may be given antimicrobial prophylaxis (such as co-trimoxazole).

How is sepsis diagnosed?

Sepsis should be considered as a time critical emergency, as

Sources and selection criteria

We searched Medline and Embase from October 2008 to October 2013 and the Cochrane Library to issue September 2013 (online) for systematic reviews and randomised controlled trials (any size) on treatment, prevention, and diagnosis and searched specified websites for guidelines using the terms sepsis, severe sepsis, septic shock, paediatric, children. Our search was updated in January 2015. Additional data sources came from authors’ institutional guidelines and policies.
Box 1 | Typical or important pathogens in sepsis

**Early onset neonatal sepsis**
- Defined as neonatal sepsis occurring in the first 72 hours of life
  - Group B streptococci, and Gram negative bacilli (especially Escherichia coli)
  - *Staphylococcus aureus* and coagulase negative staphylococci, *Haemophilus influenzae*, and *enterococci*
  - *Listeria monocytogenes* (rare)

**Late onset neonatal sepsis**
- Defined as neonatal sepsis occurring after the first 72 hours to one month of life
  - Coagulase negative staphylococci (common cause owing to the high incidence in vascular catheter associated infection in neonatal inpatients)
  - May also be caused by the same organisms responsible for early onset neonatal sepsis

**Infants and young children**
- *Streptococcus pneumoniae*
- *Neisseria meningitidis* (occurs in a bimodal age distribution, affecting young children and adolescents)
- *S aureus* and group A streptococci
- *Haemophilus influenzae* type b (important cause of sepsis worldwide, but it is rare in the developed world because of vaccination)
- *Bordetella pertussis* (although rare, may cause a severe illness in young infants before primary vaccination)
- In resource poor settings diarrhoea and pneumonia are the most common infections (and causes of death)

**Infants and children in hospital**
- Cause of hospital acquired infection depends on local bacterial epidemiology
- Coagulase negative staphylococci are usually associated with vascular catheter infection
- Meticillin resistant *Staphylococcus aureus* (MRSA)
- Gram negative organisms such as *Pseudomonas aeruginosa, Klebsiella species*, *E coli*, and *Acinetobacter* species.

**Asplenic or functional asplenia**
- Salmonella sepsis, including salmonella osteomyelitis in sickle cell disease
- Other encapsulated organisms (for example, *Streptococcus pneumoniae, Haemophilus influenzae*)

**Mosquito-borne disease**
- Malaria (*Plasmodium falciparum*), dengue virus, and *Burkholderia pseudomallei* (meliodosis)

**Other organisms**
- Fungal (for example, *Candida* species, *Aspergillus* species) and viral (for example, influenza, respiratory syncytial virus, human metapneumovirus, varicella, and herpes simplex virus) pathogens account for as many as 5.3% and 2.9% of severe sepsis in children, respectively.

In practice, the clinician should consider sepsis or septic shock if a child has a suspected or proved infection and has at least two of the following:
- Core temperature <36°C or >38.5°C (<97°F or >101°F)
- Inappropriate tachycardia (according to local criteria or advanced paediatric life support guidance)
- Altered mental state (such as sleepiness, irritability, lethargy, floppiness)
- Reduced peripheral perfusion or prolonged capillary refill.
- If in doubt, an experienced paediatrician should be consulted.

In neutropenic patients sepsis should be considered if the core temperature is >38°C (>100°F).

In all age groups, if sepsis has progressed, the patient may develop severe sepsis or septic shock. Septic shock may manifest in two main clinical pictures: cold shock and warm shock (box 3 see thebmj.com). In both shock states, the patient will show clinical signs of shock outside the cardiovascular system, the most important of which is impaired neurological function. This may manifest as irritability, apnoeas and drowsiness, obtundation, or delirium.

Children often maintain normal blood pressure even in late stages of shock; therefore, hypotension is often a terminal sign.

Purpura fulminans is a widespread non-blanching purpuric rash classically seen in meningococcaemia.

Decreased urine output is common in acutely ill children and often reflects a degree of dehydration (due to decreased intake, excessive fluid losses, or both). This is not a specific finding in sepsis.

The UK based National Institute of Health and Care Excellence (NICE) has developed a traffic light system based on clinical signs, which helps physicians assess the probability of serious illness in young children presenting with fever (www.nice.org.uk/guidance/cg160/resources/cg160-fever-ish-illness-in-children-support-for-education-and-learning-educational-resource-traffic-light-table2).

**How is sepsis managed?**
Management of sepsis in children first requires prompt recognition. A standard ABC (airway, breathing, circulation) approach with particular emphasis on early administration of antibiotics and fluid resuscitation is key in children with sepsis and septic shock.

**Treatment according to American College of Critical Care Medicine guidelines and bundles**
Compliance with guidelines or care bundles is associated with improved outcomes.

One study in the tertiary accident and emergency department at Boston Children’s Hospital looked at delivery of care. Those who received the care bundle recommended by the American College of Critical Care Medicine guidelines (early recognition of severe sepsis, vascular access, antibiotic administration, administering intravenous fluids, and vasopressors for fluid refractory shock) had a significantly shorter intensive care length of stay (mean 5.5 v 6.8 days) and hospital length of stay (mean 6.8 v 10.9 days).

Adherence to all five elements of care in this study was low at 19%. In a UK pre-intensive care unit audit, adherence to the ACCM-PALS guideline was only 38%.

Reasons for poor
Box 2: Definitions for sepsis in children* (from the International Consensus Conference on Pediatric Sepsis)

Infection
Suspected or proved infection with any pathogen

Systemic inflammatory response syndrome
Generalised inflammatory response, defined by the presence of ≥2 of the following criteria (abnormal temperature or white cell count must be one of the criteria):
- Abnormal core temperature (≥36°C or ≤38.5°C)
- Abnormal heart rate (>2 standard deviations above normal for age, or <10th centile for age if child is aged ≤1 year)
- Raised respiratory rate (>2 standard deviations above normal for age, or mechanical ventilation for acute lung disease)
- Abnormal white cell count in circulating blood (above or below normal range for age, or >10% immature white cells)

Sepsis
Systemic inflammatory response syndrome in the presence of infection

Severe sepsis
Sepsis in the presence of cardiovascular dysfunction, acute respiratory distress syndrome, or dysfunction of ≥2 organ systems

Septic shock
Sepsis with cardiovascular dysfunction persisting after at least 40 mL/kg of fluid resuscitation in one hour

Refractory septic shock
Fluid refractory septic shock—Shock persisting after ≥60 mL/kg of fluid resuscitation
Catecholamine resistant septic shock—Shock persists despite treatment with catecholamines

The following standardised definitions were initially developed by the International Consensus Conference on Pediatric Sepsis to standardise entry criteria for large multicentre clinical trials. Clinical diagnosis of sepsis must occur earlier in the care pathway than classification allows.

Airway and respiratory support

The airway and breathing should be managed as in advanced life support and resuscitation algorithms.

Oxygen should be titrated according to pulse oximetry, aiming for an oxygen saturation of >94% once the patient is haemodynamically stable. Caution should be exercised in premature neonates or neonates suspected of having congenital heart disease.

Intubation is recommended if respiratory support is required or for patients with a reduced level of consciousness.

The clinician should be prepared for cardiovascular collapse or cardiac arrest on induction of anaesthesia for intubation.

Initial fluid resuscitation

Profound fluid loss from the intravascular space occurs owing to capillary leak and may persist for several days.

The key is rapid early infusion, aiming to restore normal physiological parameters of heart rate and blood pressure. The choice of fluid is less important, provided it is isotonic. Crystalloids such as sodium chloride (0.9%) and compound sodium lactate (Hartmann's solution or lactated Ringer's solution) are commonly used and are appropriate; albumin (4.5%) may also be used. There could be theoretical advantages in using colloids for resuscitation in children with sepsis, but colloids are not favoured in adult resuscitation, and there is insufficient evidence to make a recommendation for or against colloids in children.

Fluids should be administered only in the absence of signs of fluid overload (that is, increased work of breathing, pulmonary crepitations, hepatomegaly, gallop rhythm). It would not be unusual for a child in septic shock to receive >100 mL/kg of fluid resuscitation within the first 24 hours of admission, due to fluid maldistribution, but vasoactive-inotropic support should also be considered early in fluid refractory shock.

Antibiotic therapy

Early administration of antibiotics saves lives. In adults, a study has shown that for every hour of delay in starting antibiotics in septic shock, there is an associated 7.6% increase in mortality. There are only a few similar studies in children, but there is compelling evidence that early antibiotic administration saves lives in children as well. In a retrospective study of 80 children, those who received antibiotics within 1 hour of admission were observed to have significantly lower levels of serum lactate and C reactive protein within the first 24 hours of admission. Although the study was underpowered to detect a change in mortality, the time to reversal of shock in children who received antibiotics within an hour was signifi-
**Box 4 | Diagnostic tests for sepsis (for full explanation see box online)**

**First tests to order**

- Full blood count with differential
- Serum glucose
- Blood culture

Blood culture results should be reviewed every 12 to 24 hours; most positive results will be detectable within 48 hours, and many will be positive within 24 hours.  

**Urine analysis and urine culture**—Urine analysis (urine sample for nitrites, microscopy, Gram stain, and culture) should be considered in all neonates with sepsis (although in the first week of life, a positive result in urine culture may simply reflect a severe bacteraemia). It should be considered in older children with symptoms suggestive of a urinary tract infection. Urine analysis may not be possible until after fluid resuscitation.

**Blood gases**—Although children rarely have arterial blood gases taken in the emergency department, it is often possible to obtain clinically useful information from capillary or venous blood gases.

- **Serum lactate**—Lactate is most reliably assessed using an arterial sample; venous and capillary lactate should be interpreted with caution.
- **Serum electrolytes**—Should be measured at baseline and regularly until patients improve.
- **Serum creatinine**—Increased serum creatinine is indicative of sepsis related renal failure.
- **Liver function tests**—Increased bilirubin levels (outside the neonatal age range) or increased alanine aminotransferase is suggestive of sepsis related liver dysfunction.
- **Coagulation studies**—In the context of sepsis and thrombocytopenia, abnormal results are indicative of disseminated intravascular dissemination.

**C reactive protein**—May be useful for the diagnosis and monitoring of sepsis and septic shock. Current practice varies regarding the use of C reactive protein, and clinicians should continue to use clinical judgment.

**Chest radiography**—Infants and small children with respiratory distress in the context of suspected sepsis should undergo chest radiography to assess for pneumonic changes.

**Tests to consider**

- **Lumbar puncture**—Lumbar puncture is usually contraindicated in children with severe sepsis until the patient is stabilised, as performing a lumbar puncture in severe sepsis may lead to collapse.
- **Meningococcal polymerase chain reaction (PCR) analysis**—This may help confirm the diagnosis in equivocal or suspected clinical cases of meningococcal sepsis, but it is not widely available.
- **Bronchoalveolar lavage culture**—May be considered for a child in an intensive care unit with a suspected ventilator associated pneumonia.
- **Herpes simplex virus PCR (blood and cerebrospinal fluid)**—Neonatal herpes simplex infection (either in the central nervous system or disseminated) is rare, but an important consideration in children with severe sepsis.

**Emerging tests**

- **Serum procalcitonin**—This biomarker may be useful for the diagnosis and monitoring of sepsis and septic shock, but the test is not commonly available. It is not currently considered to be the standard of care in the UK or Europe.

**Emerging biomarkers**—Other biomarkers (such as CD64, interleukin 18, mass spectrometry, specific mRNA expression) are considered emerging and are not widely used or validated yet.

---

**Temperature control**

Normothermia (36.5°C to 37.5°C (97.5°F to 99.5°F)) should be maintained. External sources of heat may be required. Conversely, hyperthermia increases metabolic demand at any age, and should be avoided.

**What is the prognosis?**

Without treatment, severe sepsis carries a mortality rate in excess of 80%. With treatment, overall mortality is approximately 10% in children up to the age of 19 years. There is no gender difference in children. Patients with pre-existing disease experience a higher mortality rate of 12.8% compared with 7.8% in previously healthy children.

Persistent shock on admission to an intensive care unit is associated with an increased odds ratio for death of 3.8. The complications of sepsis, their management and follow-up are discussed in more detail online.
