Diagnosis, management, and prevention of rotavirus gastroenteritis in children

Umesh D Parashar, E Anthony S Nelson, Gagandeep Kang

Rotavirus is the leading cause of severe childhood gastroenteritis. Each year, rotavirus is responsible for about 25 million clinic visits, two million hospital admissions, and 180 000-450 000 deaths in children under 5 years of age globally. Although rotavirus infection is prevalent worldwide, most deaths from this infection occur in developing countries (fig 1). Gastroenteritis caused by rotavirus cannot be clinically distinguished from that caused by other enteric pathogens; diagnosis requires testing of faecal specimens with commercially available assays. However, rotavirus is not routinely tested for in patients with gastroenteritis because the results do not alter clinical management, which relies mainly on appropriate rehydration therapy. Orally administered live attenuated vaccines that mimic natural infection offer the best protection against rotavirus. Two licensed rotavirus vaccines have been available since 2006 and have been implemented in many countries. We review approaches to diagnosis, management, and prevention of rotavirus gastroenteritis.

Fig 1 | World Health Organization estimates of rotavirus mortality (deaths/100 000 children under 5 years of age) by country in 2008. Reproduced, with permission, from Lancet Infectious Diseases.

SUMMARY POINTS

- Rotavirus is the leading cause of severe gastroenteritis in children worldwide, accounting for 35-40% of hospital admissions for gastroenteritis.
- Each year, 180 000-450 000 children under 5 years die from rotavirus gastroenteritis, with more than 90% of deaths occurring in developing countries.
- Because nearly all children are affected by rotavirus by age 5 years, good sanitation and hygiene alone are inadequate for prevention.
- Orally administered live attenuated vaccines offer the best protection against rotavirus; as of December 2013, national immunisation programmes of 51 countries include rotavirus vaccine. Such programmes have greatly reduced morbidity and mortality from gastroenteritis.
- A low risk of intussusception has also been documented post-licensure in some countries, but this risk is greatly exceeded by the health benefits of vaccination.

How does rotavirus gastroenteritis present clinically?

The clinical spectrum of rotavirus infection ranges from subclinical illness or mild watery diarrhoea of limited duration to frequent profuse diarrhoea with vomiting and fever that can result in dehydration with shock, electrolyte imbalance, and death. Rotavirus illness usually begins with acute onset of fever and vomiting, followed one or two days later by frequent watery stools. About 30-40% of children may have a moderate fever (temperature >39°C). Vomiting usually lasts for only one or two days and other gastrointestinal symptoms generally resolve in three to seven days.

Although gastroenteritis is the chief manifestation of rotavirus infection, neurological features—including benign convulsions (usually afebrile but febrile in some cases), encephalitis or encephalopathy, and cerebellitis—have also been described. For example, a multicentre study from Canada reported that 7% of 1359 children admitted to hospital with laboratory confirmed rotavirus had seizures at presentation. A variety of other clinical conditions (such as sudden infant death syndrome, necrotising enterocolitis, intussusception, Kawasaki’s disease, and type 1 diabetes) have been associated with rotavirus gastroenteritis, but a causal association has not been confirmed. A transient rise in serum transaminase concentrations is also often seen in patients with rotavirus gastroenteritis.

Who gets rotavirus disease?

Rotavirus infects nearly all children in developed and developing countries by 3-5 years of age. Neonatal infections occur but are often asymptomatic or mild, possibly because of protection from maternal antibody. The incidence of clinical illness peaks in children aged 4-23 months, who are also at greatest risk of severe disease that requires hospital admission. Although repeat infections are common (three or more rotavirus infections occurred in about 42% of children by 2 years of age in one follow-up study in a cohort of Mexican children), symptoms are milder with each subsequent infection. Therefore, rotavirus infections are usually subclinical or mild in adults, but they can be severe, particularly in immunocompromised and older people. Rotavirus is also an important cause of nosocomial diarrhoea.

Case-control studies in industrialised countries have...
In temperate climates, rotavirus gastroenteritis shows prominent seasonality, occurring mainly during the autumn and winter, with little disease activity during summer months. In tropical countries, rotavirus occurs all year round, although incidence often increases during the cool dry months.

How do rotaviruses cause diarrhoea?
Mechanisms of rotavirus pathogenesis have been studied in animal models and humans. The infectious dose of rotavirus is estimated to be 100-1000 viral particles. Transmission of rotavirus occurs mainly through the faecal-oral route, and viral spread can occur through contaminated hands, environmental surfaces and objects, and occasionally food and water. Rotavirus exclusively infects the mature differentiated enterocytes found at the tips of the villi in the small intestine (fig 2). Attachment of rotavirus to its sialoglycoprotein and integrin receptors is mediated mainly by viral protein 4 (VP4), but neutralising antibodies directed against VP4 do not prevent infection. NSP4 is also released with the mature virions. NSP4 induces the release of intracellular calcium (Ca\(^{2+}\)) from the endoplasmic reticulum (ER) and disrupts tight junctions, resulting in paracellular leakage of fluid and electrolytes. NSP4 can act on crypt cells to induce chloride (Cl\(^{-}\)) secretion directly or through the enteric nervous system (ENS), both of which draw water into the lumen. A decrease in brush border enzymes induced by infection results in accumulation of sugars in the lumen and osmotic fluid loss. Destruction of intestinal cells later in infection results in loss of surface area and malabsorptive diarrhoea.

To date, 11 rotavirus A (rotavirus A [RA] strain) serotypes have been identified. They are generally distributed equally among different populations and are not associated with specific human groups. Rotavirus is spread through the faecal-oral route, and viral spread can occur through contaminated hands, environmental surfaces and objects, and occasionally food and water. Rotavirus exclusively infects the mature differentiated enterocytes found at the tips of the villi in the small intestine (fig 2). Attachment of rotavirus to its sialoglycoprotein and integrin receptors is mediated mainly by viral protein 4 (VP4), but neutralising antibodies directed against VP4 do not prevent infection. NSP4 is also released with the mature virions. NSP4 induces the release of intracellular calcium (Ca\(^{2+}\)) from the endoplasmic reticulum (ER) and disrupts tight junctions, resulting in paracellular leakage of fluid and electrolytes. NSP4 can act on crypt cells to induce chloride (Cl\(^{-}\)) secretion directly or through the enteric nervous system (ENS), both of which draw water into the lumen. A decrease in brush border enzymes induced by infection results in accumulation of sugars in the lumen and osmotic fluid loss. Destruction of intestinal cells later in infection results in loss of surface area and malabsorptive diarrhoea.

shown that lack of breast feeding, prematurity, and low birth weight are associated with increased risk of hospital admission for rotavirus gastroenteritis. Protracted rotavirus diarrhoea with prolonged viral excretion and, in rare instances, systemic dissemination has been described in severely immunodeficient children, particularly those with severe T cell and B cell deficiencies. People who are immuno-suppressed in preparation for bone marrow transplantation are also at risk for severe or even fatal rotavirus disease.

In all regions of the world, rotavirus is the leading cause of hospital admission for gastroenteritis. A systematic review of 131 surveillance studies published from 2001 to 2011 found that rotavirus accounted for 33-49% of hospital admissions for gastroenteritis in countries in different geographical regions and with varying levels of child mortality. However, more than 90% of global deaths from rotavirus occur in low income countries in sub-Saharan Africa and South Asia, mainly because of suboptimal access to healthcare, including basic hydration therapy. In addition, compared with industrialised countries, severe rotavirus gastroenteritis occurs at a younger age in developing countries (up to two thirds of all paediatric disease occurs in the first year of life) and coinfections with other enteric pathogens are more common.

In temperate climates, rotavirus gastroenteritis shows prominent seasonality, occurring mainly during the autumn and winter, with little disease activity during summer months. In tropical countries, rotavirus occurs all year round, although incidence often increases during the cool dry months.
as diarrhoea resolves, but viral nucleic acid can be detected at low levels for several weeks.\textsuperscript{14} The pathogenesis of rotavirus diarrhoea includes effects on absorption and on secretion. Morphologically, rotavirus infection causes enterocyte death and desquamation, leading to the loss of absorptive villous cells and the proliferation of secretory crypt cells.\textsuperscript{15} Malabsorption may also result from a virus induced reduction in the expression of absorptive enzymes, as well as paracellular leakage as a consequence of functional changes in tight junctions between enterocytes, which may be mediated by the viral non-structural protein 4 (NSP4). Biopsies show atrophy of the villi and mononuclear cell infiltrates in the lamina propria. Increased chloroide secretion and loss of consequent water and electrolyte are mediated by NSP4, which acts as a viral enterotoxin, activating cellular calcium channels and inducing secretory diarrhoea. Activation of the enteric nervous system (also thought to be dependent on NSP4) induces secretory diarrhoea and increases intestinal motility.\textsuperscript{16} Villous brush border enzymes such as sucrase and isomalatase also decrease, resulting in accumulation of undigested sugars in the intestinal lumen. This increases the osmotic gradient, which in turn favours further fluid secretion.

Rotavirus infection was previously thought to be limited to the intestine, but several studies over the past decade have shown that rotavirus causes short term viraemia in immunocompetent infants as well as in experimentally infected animals.\textsuperscript{17} The clinical relevance of this systemic spread of rotavirus remains unclear, but it may be linked to the extraintestinal clinical manifestations associated with rotavirus infection.

**How is rotavirus diagnosed?**

Rotavirus can be detected in stool specimens from children with gastroenteritis by several techniques, including electron microscopy, polyacrylamide gel electrophoresis, antigen detection assays, reverse transcription polymerase chain reaction (RT-PCR), and virus isolation. Diagnosis of rotavirus was initially by electron microscopy, with and without agglutination by immune sera. Large numbers of rotavirus particles (up to $10^{13}$/g faeces) are excreted during the acute phase of infection, and children with severe diarrhoea seem to excrete a greater number of viruses.\textsuperscript{17} Polyacrylamide gel electrophoresis detects rotavirus RNA extracted directly from stool specimens; the electrophoretic migration pattern of the 11 segments of the double stranded RNA genome permits analysis of the relatedness of circulating strains.\textsuperscript{18}

Children with gastroenteritis are not routinely tested for rotavirus because the results do not alter treatment. When testing is performed, antigen detection tests—including commercially available enzyme linked immunosorbent assays (ELISAs) and immunochromatographic assays—are widely used. Most of these tests have high sensitivity and specificity (90-95%).\textsuperscript{17} RT-PCR is widely used in research laboratories to detect the viral genome.\textsuperscript{20} It provides data on the VP7 and VP4 genotypes that form the basis of binary classification (G and P type, respectively) of rotavirus strains.

**How is rotavirus gastroenteritis treated?**

The management of acute rotavirus gastroenteritis focuses on the treatment and prevention of dehydration. In most situations the clinician will not be aware at the start of treatment whether the gastroenteritis is caused by rotavirus or another pathogen. Initial assessment therefore focuses on determining the degree of dehydration because this will be used to guide and monitor treatment. Many evidence based reviews and clinical guidelines are available on various aspects of the assessment and treatment of acute gastroenteritis in young children.\textsuperscript{21-36} However, a recent systematic review of eight guidelines noted considerable variation in their quality, inconsistencies between the recommendations, lack of evidence for many recommendations, and lack of generalisability to general practice.\textsuperscript{33} These were suggested as possible reasons why adherence to such guidelines is poor in high income countries. For example, the authors noted that in general practice it was unclear “how” or to “whom” oral rehydration therapy should be given. They concluded that future studies, particularly in general practice, need to determine the value of clinical signs and symptoms in assessing dehydration, the optimal dose of oral rehydration solution for

each grade of dehydration, and the validity of reasons why clinicians prescribe other drugs. In contrast, another recent assessment of the quality of clinical practice guidelines for acute gastroenteritis, using the appraisal of guidelines for research and evaluation instrument, concluded that the overall quality of these guidelines was fair.38

How should dehydration be assessed?
Several scoring systems have been devised to assess dehydration.39 The World Health Organization scale is probably most widely used in the developing world (table 1),40 whereas the modified four point Gorelick score (box) and clinical dehydration scale (table 2) have been used in developed world settings.12 34 39 The clinical dehydration scale has been reported to help predict a longer length of stay and the need for intravenous fluid rehydration.32 It is generally accepted that conventional clinical signs of dehydration are valid and reliable when used collectively but individually they lack sensitivity and specificity.41 The Vesikari and Clark scores are used in rotavirus vaccine efficacy trials for assessing the severity of gastroenteritis but are not designed to guide clinical management according to the degree of dehydration.35

Oral and intravenous rehydration therapy
Oral and intravenous rehydration is the mainstay of treatment for rotavirus and other causes of acute gastroenteritis. Oral rehydration therapy is the preferred treatment of mild to moderate dehydration in children with acute diarrhea.27 29 43 For every 25 children (95% confidence interval 14 to 100) treated one will not respond and will require intravenous rehydration.27 Expert consensus recommends that children who are very ill, lethargic, drinking poorly, or have shock or near shock are initially treated intravenously. Oral rehydration therapy should not be given to children with intestinal ileus until bowel sounds are audible, or in the presence of glucose malabsorption.28

For more than two decades, WHO recommended the standard glucose based oral rehydration solution (90 mmol/L sodium, 111 mmol/L glucose, and a total osmolarity 311 mmol/L).40 However, subsequent studies have shown that when compared with the standard WHO solution, reduced osmolarity oral rehydration solution is associated with fewer unscheduled intravenous fluid infusions (odds ratio 0.59, 0.45 to 0.79), lower stool volume after randomisation, less vomiting, and no increased risk of hyponatraemia.41 In 2002, WHO recommended the routine use of a solution with reduced osmolarity (sodium 75 mmol/L, glucose 75 mmol/L, and total osmolarity 224 mmol/L) for non-cholera diarrhea.

To maintain hydration of children with “no signs of dehydration,” WHO recommends giving extra fluid or oral rehydration solution after each loose stool. The suggested volume is 50-100 mL (quarter to half a large cup) for children under 2 years of age and a 100-200 mL (half to one large cup) for those above 2.20 For children with “some signs of dehydration,” WHO recommends correcting hydration over four hours with 75 mL/kg of solution.40 However, a review of eight international guidelines showed that recommendations on the dose of oral rehydration solution were not evidence based and were inconsistent, reflecting the use of expert opinion and differences in how guidelines categorised dehydration.37 The authors concluded that the optimal regimen was unclear.

It is important that breast feeding should continue throughout the rehydration and maintenance phases of treatment.40 Feeding should be restarted as soon as possible because this will reduce the duration and severity of diarrhoea, and there is no evidence that early refeeding increases the risk of unscheduled intravenous fluid use, episodes of vomiting, or development of persistent diarrhoea.42 Although lactose-free feeds may reduce the duration of diarrhoea in children with mild to severe dehydration compared with feeds containing lactose, there is no evidence that lactose containing feeds are harmful for most children with acute gastroenteritis.42

Randomised controlled trials—including some that specifically assessed efficacy against rotavirus gastroenteritis—have shown that other treatments such as probiotics, zinc, ondansetron, nitazoxanide, and some biological compounds are effective in the management of acute gastroenteritis.21 24 40-45 However, recommendations for the use of these treatments vary considerably between different developmental regions and different countries, and further discussion of their use is beyond the scope of this article.

How can rotavirus gastroenteritis be prevented?
Because rotavirus infects nearly all children in both industrialised and developing countries early in life, good hygiene and sanitation alone are considered inadequate for prevention. Observational studies have shown that breast feeding confers protection from rotavirus gastroenteritis, although one case-control study indicated that it may only postpone

*Agues for vaccine doses vary according to the recommendations of individual countries and vaccination schedules.
Understanding the benefit-risk profile of routine rotavirus vaccination in a diverse range of geographical and socioeconomic settings

Identifying interventions (such as additional vaccine doses or alternative schedules, supplementation with micronutrients) or alternative approaches (such as parenteral vaccines) that might improve the performance of rotavirus vaccines in low income settings

FUTURE RESEARCH

Making rotavirus vaccines more effective and safe for use in children of all ages

VOLUME 348

TIPS FOR NON-SPECIALISTS

All children are infected with rotavirus in the first 3-5 years of life, regardless of hygiene and sanitation conditions

Vaccines are therefore the most effective way to prevent rotavirus diarrhoea

Treatment of rotavirus diarrhoea relies on hydration therapy

Rotavirus vaccines have performed well in countries where they are used routinely; in some settings, they have conferred additional benefits to unvaccinated children and adults through herd protection

Although rotavirus vaccines work less well in developing countries, the potential to prevent severe disease and deaths is greater because of the high disease burden in these settings

The documented health benefits of rotavirus vaccines far outweigh the small risk of intussusception that has been seen in some settings

Areas for Future Research

Exploring the role of rotavirus in extraintestinal clinical syndromes (such as neurological manifestations, necrotising enterocolitis)

Investigating the value of clinical signs and symptoms in assessing dehydration, particularly in general practice

Defining the optimal dose of oral rehydration solution for each grade of dehydration, so that consistent recommendations can be made

Identifying treatments (including antiviral agents) with clinical efficacy against rotavirus gastroenteritis

Community based action research and sociocultural research on knowledge, attitudes, perceptions, cultural practices, and health seeking behaviours with regard to rotavirus infection

Understanding the benefit-risk profile of routine rotavirus vaccination in a diverse range of geographical and socioeconomic settings

Identifying the effectiveness and impact of rotavirus vaccination in low income settings

Identifying interventions (such as additional vaccine doses or alternative schedules, supplementation with micronutrients) or alternative approaches (such as parenteral vaccines) that might improve the performance of rotavirus vaccines in low income settings

the occurrence of rotavirus gastroenteritis to the post-weaning period.66

Follow-up of birth cohorts indicates that, although children can be infected with rotavirus four to five times in the first two years of life, the incidence of severe rotavirus gastroenteritis is reduced with each repeat infection.6, 7 Therefore, orally administered, live, attenuated rotavirus vaccines have been developed to mimic the effect of natural infection and prevent severe rotavirus disease.

A rhesus-human reassortant rotavirus vaccine (Rotashield, Wyeth) was licensed in the US in 1998 after showing high efficacy against severe rotavirus gastroenteritis in randomised clinical trials.67 Rotashield was recommended for routine immunisation of US infants the same year but was abruptly withdrawn a year later because post-licensure observational studies found that it was associated with a severe adverse event, intussusception.48 49 Intussusception is a form of bowel obstruction that often requires surgery and is associated with high fatality if not treated. It was estimated that vaccination of 10 000 infants with Rotashield resulted in one excess case of intussusception.

Two other live oral rotavirus vaccines—a pentavalent bovine-human reassortant vaccine (RotaTeq, Merck) and a monovalent human vaccine (Rotarix, GSK Biologicals)—were in advanced stages of clinical testing when Rotashield was withdrawn (table 3). RotaTeq and Rotarix were each tested in randomised clinical trials of 60000-70000 infants to assess the risk of intussusception before licensure.50 51 No increase in risk was found during the 42 and 30 days post-vaccination after the three doses of RotaTeq or two doses of Rotarix, respectively. The vaccines showed 85-98% efficacy against severe rotavirus gastroenteritis in these trials conducted in the Americas and Europe, with good protection against disease caused by rotavirus strains not included in the vaccines (heterotypic immunity). These findings supported vaccine licensure and recommendations for use by policy groups in the US and Europe and by WHO.52

As of December 2013, 51 countries include rotavirus vaccines in their national immunisation programmes. A systematic review of ecological studies from eight countries reported a 49-89% decline in laboratory confirmed rotavirus hospital admissions and 17-55% reduction in all cause hospital admissions for gastroenteritis in children under 5 years within two years of vaccine introduction.53 Unexpectedly, rotavirus vaccination of young infants has also resulted in decreases in rotavirus disease in children who missed vaccination, older children, and even adults who were not eligible for vaccination.54 This phenomenon, known as herd protection, is probably related to reduced transmission of rotavirus in the community as a result of vaccination. Reductions in nosocomial rotavirus infections have also been seen since the introduction of the vaccine.55 Lastly, ecological studies from Mexico and Brazil have shown a 35% and 22% decline in childhood deaths from diarrhoea, respectively, since the introduction of the vaccine.56 57 and these reductions have been sustained for four years in Mexico. These findings are particularly noteworthy because vaccine efficacy against death from diarrhoea was not evaluated in pre-licensure trials.

Post-licensure observational studies in several countries, including the US, Australia, Mexico, and Brazil, have also identified a low risk of intussusception with both rotavirus vaccines.58 60 The evidence of risk for the two vaccines is difficult to compare directly because the study populations and designs differed. In general, the overall risk is one to five excess cases of intussusception per 100 000 vaccinated infants. Considering the substantial and well documented health benefits of vaccination against this low intussusception risk, policy makers in countries with documented risk, as well as global health authorities such as WHO, strongly support rotavirus vaccination of infants.

Live oral vaccines against many diseases, such as polio, typhoid, and cholera, have performed less well in developing countries than in industrialised ones. The reasons for this variability are not completely understood. Potential explanations include interference in vaccine uptake by greater levels of maternal antibody or concurrent enteric infections in developing countries, as well as reduced immune response in infants because of comorbidities or malnutrition, including micronutrient deficiencies.66

Because of these concerns, randomised efficacy trials of both RotaTeq and Rotarix were conducted in developing countries in Africa and Asia.62 63 These trials showed modest vaccine efficacy (50-64%) against severe rotavirus gastroenteritis. Despite this reduced efficacy, the public health
As rotavirus vaccines are introduced into immunisation programmes of low income countries globally, it will be important to assess the real world impact of vaccination to gain a better understanding of vaccine effectiveness and safety in a range of settings. Although both of the licensed rotavirus vaccines have shown good protection against a range of circulating rotavirus strains, including strains with either or both G and P types not contained in the vaccine, further monitoring of the long term impact of vaccination on strain ecology is vital. Also, given the moderate efficacy of rotavirus vaccines in low income countries, interventions to improve vaccine performance (such as additional vaccine doses or different vaccination schedules) should be considered and evaluated. Finally, to sustain global implementation of vaccination, an adequate supply of affordable rotavirus vaccines must be assured. It is therefore encouraging that several manufacturers in emerging markets, including India, China, Indonesia, and Brazil, are developing candidate rotavirus vaccines that may be available within the next five years.
