Indomethacin and Platelet Aggregation in Chronic Glomerulonephritis: Existence of Non-responders

G. DE GAETANO, J. VERMYLEN, M. B. DONATI, G. DOTREMONT, P. MICHIELSEN

British Medical Journal, 1974, 2, 301-303

Summary

Indomethacin given to adults with glomerulonephritis usually reduces their urinary excretion of protein and fibrinogen/fibrin-related (F.R.) antigen. Nevertheless, non-responders exist. Platelet aggregation is significantly more strongly inhibited by indomethacin in good responders than in non-responders. This supports the hypothesis that the reduction of urinary excretion of F.R. antigen during indomethacin administration is related, at least in part, to inhibition of intrarenal platelet aggregation and of the subsequent fibrin deposition.

Introduction

Indomethacin can greatly reduce proteinuria in patients with chronic glomerulonephritis (Michielsen and Verberckmoes, 1967; Michielsen *et al.*, 1969, 1970). Urinary fibrinogen/fibrin-related (F.R.) antigen may also be reduced significantly after the administration of indomethacin to such patients (Vermylen *et al.*, 1970, 1971), but some subjects are non-responders (Clarkson *et al.*, 1972). Intrarenal fibrin deposition often occurs in glomerulonephritis (Vassalli and McCluskey, 1965), and it has been suggested that the reduced urinary excretion of F.R. antigen after the administration of indomethacin results from decreased glomerular fibrin formation (Vermylen *et al.*, 1970; Clarkson *et al.*, 1972), possibly due to the inhibition of platelet aggregation by this drug (Vermylen *et al.*, 1970). A single dose of indomethacin (0.035-1.2 mg/kg) given to normal subjects inhibits platelet aggregation for six to eight hours (O'Brien *et al.*, 1970; Vermylen *et al.*, 1970); this effect lasts slightly longer with repeated ingestion over 48 hours (O'Brien *et al.*, 1970). The bleeding time is prolonged

but coagulation and fibrinolysis are not changed (de Gaetano *et al.*, 1971).

The present study aimed at defining the effect of long-term indomethacin administration on platelet aggregation in patients with chronic glomerulonephritis. In particular, we wanted to see whether platelet aggregation would be less inhibited in non-responders—that is, patients whose urinary excretion of F.R. antigen is not reduced by indomethacin.

Patients and Methods

Altogether 35 patients (24 men and 11 women aged 16-54 years) with histologically definite glomerulonephritis were examined. All had been taking indomethacin (75-175 mg/day) for 5 to 36 months. Blood was collected 3 to 12 hours after the last dose of indomethacin in 9 cases (group 1), 13 to 24 hours afterwards in 16 cases (group 2), and more than 24 hours afterwards in 10 cases (group 3). These three groups of patients showed no significant difference in age, proteinuria, excretion of fibrinogen-like material, creatinine clearance, or histological lesions.

Of the patients in group 2, 14 (8 men and 6 women aged 16-40 years) were further examined 60 minutes after a single 50-mg dose of indomethacin by mouth. Ten normal subjects (five men and five women) were also examined before and at different intervals after a test dose of 50 mg of indomethacin.

The 24-hour urinary excretion of F.R. antigen was determined as described (Vermylen *et al.*, 1970). Platelets were counted by phase microscopy using the Unopette (Becton-Dickinson). Platelet aggregation was studied at 37°C in a Born aggregometer using 0.8 ml of platelet-rich plasma (adjusted to about 300,000 platelets/mm³ by dilution with platelet-poor plasma from the same subject) and 0.2 ml of the following aggregation inducers: sodium salt of adenosine-5-diphosphate (Sigma) 2.10⁻⁵ mol/l; adrenaline (Stago) 50 µg/ml; undiluted Thrombofax; and a purified bovine fibrinogen preparation (Kabi) 200 mg/100 ml. All these reagents were dissolved or diluted in Michaelis buffer at pH 7.3 (Stago). The modifications of light transmission were monitored for at least 10 minutes by a recorder (Vitatron) connected to the aggregometer. The response to the platelet aggregation tests was defined as either normal or abnormal using the criteria in table I.

Results

The inhibitory effect of indomethacin on platelet aggregation was found to be maximal in the first 12 hours after ingestion,

TABLE I—Criteria for Evaluation of Response to Platelet Aggregation Tests

Aggregation Inducer	Response	
	Normal	Abnormal (Inhibition)
Adenosine-5-diphosphate	Irreversible aggregation	Disaggregation within 10 min.
Adrenaline	Two waves	Absence of second wave
Thrombofax*	Latent period shorter than 2 min; maximal slope 20-6-52-6 TU/min; maximal amplitude 30-7-59-1 TU	Latent period longer than 2 min. and/or maximal slope less than 20-6 TU/min and/or maximal amplitude less than 30-7 TU
Bovine fibrinogen†	Unique, irreversible wave or two waves	Disaggregation within 10 min or absence of second wave

*See de Gaetano *et al.* (1972).

†It has recently been shown (Forbes and Prentice, 1972, 1973; Donati *et al.*, 1973) that bovine factor VIII present in bovine fibrinogen is responsible for platelet aggregation.

TU = Transmission units.

still detectable in some patients after 13 to 24 hours, and almost completely absent after 24 hours (table II). The effect produced by the 50-mg test dose was statistically significant in both groups of subjects (table III) though it was more striking in the controls, notwithstanding the effect of previous drug administration in the glomerulonephritis group.

Patients in whom indomethacin treatment had reduced the mean urinary excretion of F.R. antigen by over half gave significantly more abnormal responses to the platelet tests before the test dose than did patients in whom the urinary excretion of F.R. antigen had been less noticeably reduced (table IV). The explanation that the latter patients may not have taken indomethacin the day before the test is invalidated by the fact that even after the test dose these patients gave significantly

fewer abnormal responses. Similar results were obtained when the patients were divided into two groups on the basis of degree of reduction of proteinuria during previous indomethacin administration (table IV); patients with a large reduction gave significantly more abnormal responses to the platelet aggregation tests both before and after the test dose than did patients with no or a slight reduction.

Platelet response was also related to the mean levels of proteinuria (table V) and creatinine clearance (table VI) during the treatment with indomethacin (mean follow-up 7.9 months). Patients with a mean proteinuria below 6 g/24 hr showed a statistically significant number of modifications of their responses to the platelet aggregation tests after the test dose, whereas patients with a proteinuria of over 6 g/24 hr did

TABLE II—Effect of Indomethacin on Distribution of Normal and Abnormal Responses to Platelet Aggregation Tests in Glomerulonephritis Patients

Group	Time Since Last Dose of Indomethacin	No. of Subjects	No. of Tests	No. of Subjects with:			Overall No. of Tests producing:	
				Completely Normal Response	1 or 2 Abnormal Responses	3 or 4 Abnormal Responses	Normal Response	Abnormal Response
1	3-12 Hours	9	36	3	1	5	18	18
2	13-24 Hours	16	64	7	6	3	43	21
3	More than 24 Hours	10	34	8	2	0	32	2
Controls		10	35	9	1	0	34	1

Statistical evaluation of overall results (last column) was as follows—Group 1 v. group 2: $\chi^2 = 2.2$, N.S.; group 1 v. group 3: $\chi^2 = 14.6$, $P < 0.001$; group 2 v. group 3: $\chi^2 = 7.5$, $P < 0.01$; group 1 v. controls: $\chi^2 = 17.79$, $P < 0.001$; group 2 v. controls: $\chi^2 = 10.08$, $0.01 > P > 0.001$.

TABLE III—Effect on Platelet Aggregation of 50-mg Test Dose of Indomethacin by Mouth in 10 Normal Subjects and in 14 Glomerulonephritis Patients already on this Drug

	Controls (35 Tests)		Patients (56 Tests)	
	No. of Normal Responses	No. of Abnormal Responses	No. of Normal Responses	No. of Abnormal Responses
Before test dose	34	1	34	22
After test dose	6	29	18	38
Significance	$\chi^2 = 42.53$; $P < 0.001$		$\chi^2 = 8.1$; $P < 0.01$	

TABLE IV—Responses of Urinary F.R. Antigen Excretion and Proteinuria to Prolonged Indomethacin Administration and Platelet Response to Test Dose

	Platelet Tests Before Test Dose		Platelet Tests After Test Dose	
	No. of Normal Responses	No. of Abnormal Responses	No. of Normal Responses	No. of Abnormal Responses
F.R. Antigen reduced $> 50\%$ (6 patients)	9	15	2	22
F.R. Antigen reduced $< 50\%$ (8 patients)	25	7	16	16
Significance	$\chi^2 = 7.9$; $P < 0.01$		$\chi^2 = 9.1$; $P < 0.01$	
Proteinuria reduced $> 50\%$ (6 patients)	10	14	3	21
Proteinuria reduced $< 50\%$ (8 patients)	24	8	15	17
Significance	$\chi^2 = 5.1$; $P < 0.05$		$\chi^2 = 5.9$; $P < 0.05$	

TABLE V—Relation between Proteinuria and Platelet Response to Test Dose of Indomethacin in Glomerulonephritis Patients

	Platelet Tests in 7 Patients with Proteinuria > 6 g/24 hr		Platelet Tests in 7 Patients with Proteinuria > 6 g/24 hr	
	No. of Normal Responses	No. of Abnormal Responses	No. of Normal Responses	No. of Abnormal Responses
Before test dose	15	13	19	9
After test dose	5	23	13	15
Significance	$\chi^2 = 6.3$; $P < 0.05$		$\chi^2 = 1.8$; N.S.	

TABLE VI—Relation between Creatinine Clearance and Platelet Response to Test Dose of Indomethacin in Glomerulonephritis Patients

	Platelet Tests in 8 Patients with Creatinine Clearance > 60 ml/min		Platelet Tests in 6 Patients with Creatinine Clearance < 60 ml/min	
	No. of Normal Responses	No. of Abnormal Responses	No. of Normal Responses	No. of Abnormal Responses
Before test dose	19	13	15	9
After test dose	8	24	10	14
Significance	$\chi^2 = 6.4$; $P < 0.05$		$\chi^2 = 1.3$; N.S.	

not. Similar findings were obtained with mean creatinine clearance values above and below 60 ml/min. The six patients whose creatinine clearance had decreased by more than 50 ml/min a year before starting treatment with indomethacin (estimated from the duration of proteinuria and the creatinine clearance when first admitted to our hospital; Dotremont *et al.*, 1973) did not show a significantly increased number of modified responses to the platelet aggregation tests after the test dose, whereas the eight patients with a less rapid decline of renal function did.

Inhibition of platelet aggregation after the addition of different concentrations of indomethacin to platelet-rich plasma was also studied. In three patients in whom the proteinuria and urinary excretion of F.R. antigen had responded well to indomethacin administration platelet aggregation was inhibited by indomethacin up to final concentrations of between 3.5×10^{-6} and 3.5×10^{-7} mol/l. (healthy controls $1.7-3.5 \times 10^{-6}$ mol/l.). In one out of three non-responsive patients platelet aggregation was not inhibited by 3.5×10^{-4} mol of indomethacin per l., and in another 3.5×10^{-5} mol of indomethacin per l. had no effect; in the third, however, the in-vitro response of platelet aggregation to indomethacin was normal.

Discussion

Glomerulonephritis patients on long-term treatment with indomethacin gave normal responses to platelet aggregation tests when the last dose of the drug was taken over 24 hours previously, confirming the observation of O'Brien *et al.* (1970) that the administration of indomethacin over long periods only slightly prolongs its effect on platelet aggregation and indicating that baseline platelet aggregation in these patients is normal.

A notable observation was that after a test dose of indomethacin the platelet response in the glomerulonephritis group as a whole seemed less striking than in the controls. When the patients with glomerulonephritis were then subdivided according to previous response of proteinuria or urinary excretion of F.R. antigen to indomethacin it became apparent that those patients in whom these indices had responded well had shown significantly more abnormal platelet responses both before and after the test dose than had the group in whom proteinuria and urinary excretion of F.R. antigen had not responded adequately. Thus non-response of proteinuria and urinary excretion of F.R. antigen to indomethacin ingestion in glomerulonephritis patients is associated with a decreased in-vivo inhibition of platelet aggregation by this drug.

This decreased in-vivo inhibition of platelet aggregation by indomethacin in some glomerulonephritis patients may be

explained in several ways. While very little is known about the absorption and elimination of this drug in glomerulonephritis reduced plasma levels may be the explanation. The experiments in which indomethacin was added to platelet-rich plasma from the patients, however, suggest that this cannot be the only explanation. That metabolic factors are implicated seems obvious from the finding that poor response is associated with severe proteinuria, lowered creatinine clearance, and previous rapid decline in renal function. Moreover, Bang *et al.* (1973) showed that platelet aggregation is enhanced in some patients with glomerular renal disease. This enhanced effect was significantly correlated with the degree of proteinuria, and they suggested that plasma proteins inhibiting platelet aggregation may be lost in the urine.

The fact that indomethacin reduces urinary excretion of F.R. antigen and strongly inhibits platelet aggregation in vivo supports but does not prove our hypothesis that the reduction of urinary excretion of F.R. antigen is related, at least in part, to inhibition of intrarenal platelet aggregation and of the subsequent fibrin deposition.
