CLINICAL RESEARCH

Relation of angiographically defined coronary artery disease to plasma lipoprotein subfractions and apolipoproteins

N E MILLER, F HAMMETT, S SALTISI, S RAO, H VAN ZELLER, J COLTART, B LEWIS

Abstract

The relation of coronary artery disease to plasma lipoproteins was examined in 104 men aged 35-65 years undergoing coronary angiography for suspected myocardial ischaemia. A score reflecting the number, degree, and length of stenoses in seven major coronary arteries was assigned to each angiogram. Lipid concentrations in lipoprotein subfractions were measured after preparative ultracentrifugation; plasma apolipoprotein concentrations were measured by electroimmunoassay.

Men with high coronary scores tended to have lower plasma high-density lipoprotein (HDL) cholesterol concentrations and higher low-density lipoprotein (density 1.019-1.063 g/ml) cholesterol concentrations than subjects of similar age with low coronary scores ($p \approx 0.1$). The strongest relation, however, was with the cholesterol concentration in the HDL₂ subfraction (density 1.063-1.125 g/ml) of HDL, which averaged 44% lower in the severely affected patients ($p < 0.005$). No associations were found between the coronary score and HDL₃ cholesterol, the cholesterol content of lipoproteins of density < 1.019 g/ml, plasma triglyceride, or the concentrations of apolipoproteins AI, AII, and E.

The high coronary scores associated with low HDL₂

concentrations reflected an increase in the number of both partial and complete stenoses distributed throughout the coronary tree. In contrast the sizes of the lesions and the proportion producing complete occlusion were unrelated to HDL₂.

Introduction

Epidemiological studies have established that the prevalence and incidence of clinical ischaemic heart disease in Western communities are correlated positively with the plasma low-density lipoprotein (LDL) concentration and negatively with the high-density lipoprotein (HDL) cholesterol concentration.¹⁻⁵ Angiographic studies have shown that the severity of coronary artery disease also increases with increasing LDL concentration and with decreasing HDL concentration.⁶⁻⁸ Both of these classes of plasma lipoproteins are heterogeneous. LDL, as originally defined, is composed of two major subfractions, LDL₁ (or intermediate-density lipoprotein) and LDL₂, the first subfraction having the lower density and the higher ratio of triglyceride to cholesterol.⁹ HDL is also composed of two major subfractions, HDL₂ and HDL₃; HDL₂ is the minor subfraction but has the greater ratio of cholesterol to protein.⁹ Metabolic studies indicate that LDL₂ is normally derived from the catabolism of LDL₁¹⁰; HDL₂ may be produced by the fusion of HDL₃ with the surface remnants of triglyceride-rich lipoproteins.¹¹

There are no published data on the relation of angiographically defined coronary artery disease to LDL and HDL subclasses. Such information could be of value in two ways. Firstly, identifying correlations of greater strength than those already recognised might improve our ability to assess the risk of ischaemic heart disease in individual subjects. Secondly, and more important, it might help to clarify the nature of the link between lipoprotein metabolism and atherogenesis. We have therefore measured the plasma concentrations of lipoprotein subfractions in patients undergoing coronary angiography. We also examined the relation of coronary disease to several apolipoproteins.

Subjects and methods

The subjects were 104 men aged 35-65 years admitted to St Thomas's Hospital for coronary angiography for suspected ischaemic heart disease. Consecutive patients were studied, with the exception that those taking lipid-lowering agents or with valvular disease or a history of diabetes mellitus or coronary artery surgery were excluded. Several other patients were omitted because the recovery of plasma cholesterol during lipoprotein fractionation was less than 95%. Plasma cholesterol and triglyceride concentrations were in the ranges 4.0-8.0 mmol/l (154-309 mg/100 ml) and 0.8-3.5 mmol/l (71-310 mg/100 ml), respectively.

ANGIOGRAPHY

Coronary angiography was performed after passage of a Judkins pigtail catheter via the right femoral artery. The overall severity of disease was evaluated by assigning to the angiogram a score reflecting the number, degree, and length of stenoses in seven major vessels (right, posterior descending, left main, left anterior descending, circumflex, and the two obtuse marginal arteries). Each stenosis identified was given one score for the degree of narrowing (<24%, 1; 25-49%, 2; 50-74%, 3; 75-99%, 4) and another for its length (<5 mm, 1; 5-10 mm, 2; >10 mm, 3). When an artery was completely occluded a score of 5 or 6 was given, the score of 5 being assigned when there was visible blood flow distal to the obstruction via collaterals. The sum of scores for all stenoses was then termed the coronary score; values ranged from 0 to 48.

PLASMA LIPOPROTEINS

Blood was collected after a 14-hour overnight fast into disodium EDTA (2.7 mmol/l; 1 mg/ml). A 5 ml aliquot of plasma was adjusted to a density of 1.019 g/ml with aqueous NaCl-NaBr, centrifuged at 105 000 *g* for 20 hours at 14°C, and the supernatant containing very-low-density lipoproteins (VLDL; density <1.006 g/ml) and LDL₁ (density 1.006-1.019 g/ml) isolated by tube slicing.¹² The LDL₂ (density 1.019-1.063 g/ml) in the infranant was precipitated with heparin and MnCl₂ (final concentrations 205 U/ml, 92 mmol/l).¹³ The supernatant (containing HDL) was then adjusted to a density of 1.125 g/ml with NaBr, centrifuged at 105 000 *g* for 40 hours, and the new supernatant (containing HDL₂; density 1.063-1.125 g/ml) isolated by tube slicing. The cholesterol concentrations in whole plasma, HDL, HDL₂, and lipoproteins of density <1.019 g/ml were measured directly by enzymatic procedures (Boehringer-Mannheim, Catalogue No 187 313); HDL₂ cholesterol (density 1.125-1.21 g/ml) and LDL₂ cholesterol were calculated by difference. Triglyceride in whole plasma and lipoproteins of density <1.019 g/ml were measured enzymatically (Boehringer-Mannheim, Catalogue No 166 448). The ratio of cholesterol to triglyceride in lipoproteins of density <1.019 g/ml was used as an index of LDL₁ concentration.⁹

The plasma concentrations of the major protein components of HDL, apolipoproteins AI and AII, were assayed by rocket immunoelectrophoresis against rabbit antiserum to purified human apolipoproteins¹⁴; apolipoprotein E, a component of VLDL, LDL₁, and HDL, was also measured.¹⁴ Standard curves were constructed using serial dilutions of plasma pools of known apolipoprotein content.

The angiographic and lipoprotein measurements were made by different investigators, neither of whom knew the results of the other.

Results

The relation of coronary disease to the different measurements was examined by dividing the subjects into three groups based on the coronary scores: group 1 were those in the bottom fifth of scores (range 0-10; *n* = 21), group 2 those in the middle three-fifths (*n* = 63), and group 3 those in the top fifth (range 31-48; *n* = 20). There were no significant differences between these groups in the usage of adrenergic beta-blocking agents, which are known to influence plasma lipoproteins.¹⁵

Table I gives the ages, body weights, systolic blood pressures, and plasma lipoprotein lipid and apolipoprotein concentrations in the three groups. Analysis by *t* test (two-tailed) showed that subjects with severe disease (group 3) had significantly lower concentrations of HDL₂ cholesterol than subjects in group 2 (*p* = 0.01) and group 1 (*p* = 0.005). The only other significant difference was a lower LDL₂

Cholesterol of density <1.019 g/ml (mmol/l)	1.01 ± 0.12	1.18 ± 0.08	1.08 ± 0.13
LDL ₂ cholesterol (mmol/l)	3.00 ± 0.24	3.50 ± 0.11	3.45 ± 0.20
Total HDL cholesterol (mmol/l)	1.29 ± 0.08	1.24 ± 0.05	1.11 ± 0.07
HDL ₂ cholesterol (mmol/l)	0.27 ± 0.03	0.23 ± 0.02	0.15 ± 0.02
HDL ₃ cholesterol (mmol/l)	1.02 ± 0.09	1.00 ± 0.05	0.95 ± 0.10
Cholesterol:triglyceride in density <1.019 g/ml	1.08 ± 0.09	1.08 ± 0.06	1.07 ± 0.14
Apolipoprotein AI	108.00 ± 19.00	123.00 ± 4.90	110.00 ± 9.00
Apolipoprotein AII	38.00 ± 3.30	39.00 ± 2.20	41.00 ± 4.30
Apolipoprotein E	5.20 ± 0.18	4.90 ± 0.08	4.90 ± 0.13

Student's *t* test (two-tailed)—Group 1 *v* group 3: HDL₂ cholesterol, *p* = 0.005; total HDL cholesterol, *p* = 0.09; LDL₂ cholesterol, *p* = 0.14. Group 1 *v* group 2: LDL₂ cholesterol, *p* = 0.04. Group 2 *v* group 3: HDL₂ cholesterol, *p* = 0.01. Other differences may have occurred by chance (*p* > 0.20).

Conversion: SI to traditional units—Triglyceride: 1 mmol/l ≈ 88.5 mg/100 ml. Cholesterol: 1 mmol/l ≈ 38.6 mg/100 ml.

cholesterol concentration in group 1 than in group 2 (*p* = 0.04). Patients in group 1 also tended to have higher total HDL cholesterol concentrations and lower LDL₂ cholesterol concentrations than those in group 3, but these associations were not as strong (*p* ≈ 0.1).

Comparison of groups 1 and 3 by the non-parametric Mann-Whitney U test gave similar results to those obtained with the *t* test: HDL₂ cholesterol, *p* < 0.002; total HDL cholesterol, *p* ≈ 0.05; LDL₂ cholesterol, *p* ≈ 0.10.

Of several lipoprotein combinations examined, the best discriminator between subjects with severe disease and those with minimal disease was the ratio of HDL₂ cholesterol to LDL₂ cholesterol (table II). In the pooled data the correlation coefficient between the HDL₂:LDL₂ ratio and coronary score was -0.23 (*p* < 0.02).

TABLE II—Lipoprotein cholesterol ratios in patients with differing degrees of coronary artery disease. Figures are means ± SEM

	Group 1 (<i>n</i> = 21)	Group 2 (<i>n</i> = 63)	Group 3 (<i>n</i> = 20)
HDL cholesterol:LDL ₂ cholesterol	0.472 ± 0.051	0.401 ± 0.035	0.347 ± 0.042
HDL ₂ cholesterol:HDL ₃ cholesterol	0.348 ± 0.072	0.278 ± 0.021	0.170 ± 0.021
HDL ₂ cholesterol:LDL ₁ cholesterol	0.106 ± 0.017	0.078 ± 0.007	0.044 ± 0.004

Student's *t* test (two-tailed)—Group 1 *v* group 3: HDL:LDL₂, *p* = 0.069; HDL₂:HDL₃, *p* = 0.035; HDL₂:LDL₁, *p* = 0.0024.

The association between HDL₂ and coronary disease was explored further by comparing patients in the top and bottom fifths of values for HDL₂ cholesterol concentration with respect to the number, nature, and distribution of stenoses. Table III gives the results. Patients with low HDL₂ concentrations had a much greater number of stenoses (by 2.4-fold; *p* < 0.002). The additional lesions were widely distributed, increasing the number of affected arteries per

†Only two patients had more than one occlusion; both had low HDL₂ concentrations.

‡Of the seven arteries examined.

Conversion: SI to traditional units—Cholesterol: 1 mmol/l ≈ 38.6 mg/100 ml.

patient ($p < 0.01$). Low concentrations were also associated with a greater prevalence of complete occlusions ($p < 0.02$). On the other hand, the relative numbers of complete and partial stenoses and the average size of the partial stenoses (length and degree of narrowing) appeared to be unrelated to HDL₂ concentration.

Discussion

The major finding in this study was that the inverse relation between clinical ischaemic heart disease and plasma total HDL cholesterol, previously shown epidemiologically,¹⁻⁵ reflects an association between the severity of coronary artery disease and the cholesterol concentration in the HDL₂ subclass. Coronary disease was also directly related to the LDL₂ cholesterol concentration, but this association was weaker than that with HDL₃. These two relations were independent of each other, the HDL₂:LDL₂ ratio being a better predictor of disease than either measurement alone. No other statistically significant associations were found. In particular, the coronary score was unrelated to age, body weight, and plasma triglyceride concentration, variables with which the total HDL cholesterol concentration has been shown to correlate in epidemiological studies.^{3 5 16}

Closer examination of the angiographic data showed that the high coronary scores associated with low HDL₂ concentrations reflected an increase in the number of stenoses. This was true for both partial and complete stenoses. The additional lesions were widely distributed, showing no preference for any particular vessel. On the other hand, the average sizes of the lesions and the proportion that had progressed to produce a complete occlusion appeared to be unrelated to HDL₂ concentration. Thus low HDL₂ concentrations may be associated with an increased susceptibility to atherosclerotic lesions but not with an acceleration of the later stages of atherogenesis or with a predisposition to secondary thrombosis. Clearly, necropsy studies will be needed to confirm or refute this. Although the severity of atherosclerosis in coronary arteries showed a negative correlation with HDL cholesterol in the necropsy study of Solberg *et al*,¹⁷ these workers did not distinguish between complicated and uncomplicated lesions or measure HDL subfractions.

Our conclusion that it is principally HDL₂ cholesterol rather than HDL₃ cholesterol to which coronary disease is related is consistent with other published observations. In a 10-year prospective study of men aged 20-66 years reported in 1966 the mean HDL₂ concentration (measured by analytical ultracentrifugation) in 38 subjects who developed clinical ischaemic heart disease was 32% lower ($p < 0.01$) than that in 1961 controls; the case-control difference in HDL₃ concentration was substantially less (-8%).¹⁸ Later Albers *et al*¹⁹ noted that patients with a history of myocardial infarction had significantly lower ratios of HDL cholesterol to apolipoprotein AI than did healthy controls, consistent with a lower HDL₂:HDL₃ ratio in the former group. It has long been recognised that the low total HDL concentrations associated with hypertriglyceridaemia, male sex, and obesity chiefly reflect low HDL₂ concentrations.²⁰

Our evidence for a positive association between coronary disease and LDL₂ cholesterol is consistent with and extends reports that angiographically defined disease is correlated with total LDL cholesterol.⁶⁻⁸ The absence of any relation between coronary disease and the cholesterol content of lipoproteins with a density below 1.019 g/ml suggests that there was no association with LDL₁ concentration in our subjects. There is little doubt that the very high LDL₁ concentrations of familial type III hyperlipoproteinaemia contribute to the premature onset of atherosclerosis in that condition.²¹ In the rest of the community, however, the LDL₁ concentration may not be a significant determinant of atherogenesis, though a high concentration produced locally at the arterial endothelial surface has been the subject of a plausible aetiological hypothesis.²²

Our failure to discover a relation between coronary disease

and the plasma concentrations of the major HDL apolipoproteins AI and AII is consistent with evidence that any reduction of apolipoprotein AI concentration in coronary victims is less than that of HDL cholesterol.¹⁹ Apolipoprotein AI also appears to be a weaker predictor of coronary events than HDL cholesterol.²³ Avogaro *et al*,²⁴ however, concluded that the concentrations of apolipoproteins AI and B (the major protein component of LDL) were more powerful than the plasma HDL cholesterol and total cholesterol concentrations in discriminating between patients with a myocardial infarction and healthy controls.

Clinically our data suggest that assessing clinical coronary risk in a person is likely to be more accurate if based on the HDL₂ cholesterol and LDL₂ cholesterol concentrations than if based on the total HDL and plasma or total LDL cholesterol values. Biochemically the association of coronary disease with low HDL₂ concentrations may provide clues to the nature of the relation between HDL metabolism and atherogenesis. HDL₂ may be produced by the fusion of HDL₃ with surface remnants liberated from triglyceride-rich lipoproteins during their catabolism by lipoprotein lipase.¹¹ This phenomenon appears to underlie the positive correlation between tissue lipoprotein lipase activity and HDL cholesterol concentration.²⁵ Thus a high HDL₂ concentration may reflect an efficient lipolytic process, perhaps reducing the intravascular residence time of certain atherogenic intermediates. Also noteworthy is that HDL₂ contains a particle which is rich in apolipoprotein E and that this competes with LDL₂ for receptor-mediated uptake by peripheral cells.²⁶ Though we found no association between the severity of disease and the plasma apolipoprotein E concentration, only a proportion of this apolipoprotein resides in HDL.²⁷

We are indebted to Dr P Alaupovic, of the Laboratory of Lipid and Lipoprotein Studies, Oklahoma Medical Research Foundation, and to Dr J J Albers, of the University of Washington, Seattle, for standardising the plasma pools used for the electroimmunoassays of apolipoproteins AI, AII, and E. This work was supported by a grant from the research endowments committee of St Thomas's Hospital. Ms C Whiting provided skilled technical help.

Hepatic vascular lesions associated with dacarbazine treatment

M A GREENSTONE, PAULINE M DOWD, D P MIKHAILIDIS, P J SCHEUER

Abstract

Dacarbazine is widely used in the treatment of melanoma. Transient abnormalities of liver function tests are well-recognised side effects of the drug, but acute liver failure due to vascular occlusion in patients receiving single-agent chemotherapy with dacarbazine has been noted only rarely. Two cases are reported in which hepatic vascular lesions developed during treatment with dacarbazine and were confirmed at necropsy.

Hepatic vascular occlusion due to treatment with dacarbazine may be less rare than was previously thought. Greater caution may be needed when dacarbazine is prescribed, particularly as an adjuvant agent in stage I and II disease.

Introduction

Dacarbazine (dimethyl-triazeno-imidazole-carboxamide) has been widely used in the treatment of stage III melanoma and in trials of adjuvant chemotherapy in patients with stage I and II disease with a poor prognosis. We report two cases in which hepatic vascular lesions occurred during dacarbazine treatment.

Case reports

CASE 1

A 53-year-old Caucasian man developed histologically proved lymph-node metastases five years after wide excision of primary melanoma. In April 1978 he began treatment with dacarbazine (250 mg/m² daily for five days). He was also taking amitriptyline (Lentizol) 50 mg at night and chlorpromazine as required as an antiemetic. Apart from transient fever on the fifth day, he tolerated treatment well. One month later he was readmitted for a second course of dacarbazine. He was well, and clinical examination, full blood count, urea and electrolyte concentrations, and liver function tests were all normal. His medication was as before. He remained well until the fourth day of treatment, when he developed acute abdominal pain and hepatic tenderness. He deteriorated with confusion, jaundice, and hypotension. Results of liver function tests became extremely abnormal (aspartate transaminase activity 1780 U/l, alkaline phosphatase activity 148 IU/l, total bilirubin 77 µmol/l (4.5 mg/100 ml)), and he developed prolonged prothrombin and partial thromboplastin times, hypoglycaemia, and a profound metabolic acidosis. A peripheral blood film showed only mild neutrophilia (74% of 13.9 × 10⁹/l), whereas a differential white cell count two days earlier had shown eosinophilia of 17% of 7 × 10⁹/l. Blood cultures were repeatedly negative. Despite vigorous supportive treatment he died 72 hours later.

At necropsy the liver had a mottled red appearance and irregular areas of necrosis were seen. The main hepatic and portal veins were patent. On microscopy recent infarcts were associated with fresh thrombi in hepatic vein branches. Vein walls and portal tracts were infiltrated with lymphocytes and eosinophils. There was a microscopic metastasis in one lung.

CASE 2

A 46-year-old Caucasian man was treated with dacarbazine 500 mg intravenously daily for five days for metastatic melanoma. He tolerated the first course of treatment well but on the third day of the second course developed clinical and laboratory manifestations of acute hepatic necrosis. There was no clinical evidence of drug hyper-
