Severe acquired immunodeficiency in European homosexual men

J GERSTOFT, A MALCHOW-MØLLER, I BYGBJERG, E DICKMEISS, C ENK, P HALBERG, S HAAHR, MARIANNE JACOBSEN, K JENSEN, J MEJER, J O NIELSEN, H K THOMSEN, J SØNDERGAARD, I LORENZEN

Abstract

Four previously healthy Danish homosexual men developed Kaposi's sarcoma or opportunistic infections with fever of unknown origin and lymphadenopathy. One patient died of a *Pneumocystis carinii* pneumonia. Three patients had defective cell-mediated immunity with absent leucocyte interferon production and decreased proliferative response to mitogens and antigens. T lymphocyte helper subsets and natural killer cell activity were reduced. Unstimulated mononuclear cells produced leucocyte migration inhibitor factor. Two patients were sexual partners and three had never been to the USA, where cases of severe acquired immunodeficiency have been reported. Thus, the syndrome must also be suspected in European homosexual men who present with fever of unknown origin, opportunistic infections, or Kaposi's sarcoma.

Introduction

During the past eight months an increasing number of cases of Kaposi's sarcoma and opportunistic infections have been reported among previously healthy homosexuals in the United States.¹⁻³ The symptoms include persistent fever, weight loss, general lymphadenopathy, and splenomegaly. About half of the patients developed Kaposi's sarcoma, which is rare in the West, except in patients receiving long-term immunosuppressive treatment.⁴⁻⁵ Others contracted opportunistic infections, among which *Pneumocystis carinii* pneumonia was the most common. Immunological studies showed a severe defect in cellular immunity,⁶⁻⁸ which may have been a primary factor leading to secondary opportunistic infections and Kaposi's sarcoma. Cytomegalovirus infections may be of pathogenetic importance, but other factors probably also play a part.⁹ The syndrome has the characteristics of an epidemic in the USA.³ All previously reported cases were in patients living in the USA, except one who made regular visits.¹⁰ We report four Danish cases with all the characteristics of those in the USA, which indicates that the syndrome has spread to Europe. Results of some immunological studies are also presented.

Patients and methods

The four patients were admitted to Hvidovre Hospital between August 1980 and December 1981. The hospital serves a population of 200 000 from the urban part of Copenhagen.

IMMUNOLOGICAL STUDIES

Mononuclear cells were obtained from heparinised venous blood. Lymphocyte cell markers were identified (a) by the percentage of cells rosetting with untreated sheep red blood cells (E-rosettes)¹¹; (b) by the percentage of membrane-bound immunoglobulin-positive cells using fluorescein-conjugated polyvalent rabbit anti-human immunoglobulins¹² (Dakopatts, Denmark); and (c) the percentage of T lymphocytes (helper/inducer cells) (Leu 3a) and T lymphocytes (cytotoxic/suppressor cells) (Leu 2a) by indirect immunofluorescence using the hybridoma-derived biotin-conjugated anti-Leu 3a and anti-Leu 2a antibodies (Becton-Dickinson, USA) and fluorescein-coupled avidin (Becton-Dickinson, USA).

Functional tests included responses to phytohaemagglutinin, concanavalin A, pokeweed mitogen, and cytomegalovirus measured by ^{14}C -thymidine incorporation.^{13,14} Natural killer cell activity and activity as effector cells in antibody-dependent cellular cytotoxicity in ^{51}Cr -release assays were measured. The Molt-4 cell line (kindly provided by Dr Mikael Jondal, Karolinska Institute, Stockholm) were used as target cells in the assay for natural killer cell activity¹⁵ and IgG-coated DBA-2 mouse mastocytoma cells as target cells in the assay for antibody-dependent cellular cytotoxicity.¹⁶ Lytic units (one unit representing the number of cells giving a cytotoxicity of 25%) were calculated as described by Cerottini and Brunner.¹⁷ Lytic activity was measured by the number of lytic units/ 10^6 mononuclear cells. Monocyte function tests,¹⁸ interferon production studies,¹⁴ leucocyte migration inhibitory factor tests,¹⁹ and purine enzyme assays²⁰ were performed as described.

Antibodies to cytomegalovirus and *Chlamydia trachomatis* were determined by complement-fixation tests.

Results

The clinical data are summarised in table I and the results of the immunological studies in table II. (Data for case 1 in table II were not

available.) In cases 2 and 3 immunological investigations were also performed at an earlier stage and gave results which were identical with those given in table II.

Case reports

Case 1—A 27-year-old homosexual man with a two-month history of fever and weight loss was seen in May 1981. He had previously been well, apart from having secondary syphilis four years earlier, which had been adequately treated. He took amyl and butyl nitrites regularly and had not visited the USA. He had generalised lymphadenopathy, violaceous lesions on the palate, and oral thrush. Ten small violaceous, non-raised lesions were present on the face and upper limbs. Chest x-ray films showed no abnormalities. Biopsy of the cutaneous and mucous lesions confirmed Kaposi's sarcoma. *Neisseria gonorrhoeae* and *Candida albicans* were cultured from the rectum and pharynx respectively. He was treated with ampicillin and mycostatin and transferred to another hospital for cancer chemotherapy. He died five months later of *Pneumocystis carinii* pneumonia. At necropsy the lesions of Kaposi's sarcoma were found in the skin, palate, hypopharynx, and paratracheal lymph nodes.

Case 2—A 50-year-old homosexual man was referred in January

TABLE I—Clinical features and laboratory findings in four Danish homosexual men with acquired immunodeficiency

	Case 1	Case 2	Case 3	Case 4
Age (years)	27	50	37	31
Sexual contacts	Case 3		Case 1	
Drug abuse	Nitrites	Nitrites	Nitrites	None
Fever, weight loss, anaemia, universal lymphadenopathy*	Present	Present	Present	Present
Skin/mucosal lesions suggestive of Kaposi's sarcoma	Present	Absent	Absent	Absent
Duration of disease (months)	5	12	23	12
Hepatitis B surface antigen	Negative	Negative	Negative	Negative
Cytomegalovirus titre	ND	1/128	1/64	1/128
<i>Chlamydia trachomatis</i> titre (lymphogranuloma test)	Negative	Negative	1/120	Negative
Serological examination for syphilis	Negative	Negative	Negative	Negative
Clinical and pathological findings	Kaposi's sarcoma, <i>P. carinii</i> pneumonia, oral candidosis	Kaposi's sarcoma, amoebic dysentery	<i>Clostridium difficile</i> colitis, anal ulcers	Oral candidosis
Present condition	Died	Alive, clinically well	Alive, not improved	Alive, not improved

*Soft, non-tender, non-adherent glands measuring up to 2×3 cm. ND = Not determined.

TABLE II—Immunological results (January 1982)

	Case 2	Case 3	Case 4	Normal range
White cell count (cells $\times 10^9/\text{l}$)	10.5	2.8	4.7	3.0–9.0

Immune complexes	Present	Absent	Absent	

ND = Not determined; LIF = Leucocyte migration inhibitory factor.

1981 because of lymphadenopathy, fever, and weight loss. He had previously been well apart from adequately treated syphilis and gonorrhoea. At the beginning of 1980 he developed chronic diarrhoea. He had been to New York twice early in 1980 and sniffed amyl and butyl nitrites regularly. Physical examination was normal apart from generalised lymphadenopathy. There were no Kaposi's eruptions on the skin or oral mucosa. Radiographic examination of the chest was normal. Rigid sigmoidoscopy showed haemorrhagic proctitis, and *Entamoeba histolytica* was found in the faeces on two separate occasions. Biopsy of the lymph nodes from the upper limb and inguinal region showed typical evidence of Kaposi's sarcoma. The patient was treated with metronidazole twice. At present he is clinically well and not receiving any chemotherapy; the lymphadenopathy persists.

Case 3—A 37-year-old homosexual man was seen in August 1980 because of persistent fever and arthralgia. He had previously been well apart from adequately treated syphilis and gonorrhoea. The patient in case 1 had been his regular sexual partner. He had never been to the USA but sniffed amyl and butyl nitrites frequently. On physical examination he appeared chronically ill with generalised lymphadenopathy, moderate enlargement of the spleen, and fine rales over both lungs. Chest x-ray films showed infiltration of both lungs. Apart from oral candidosis microbiological examination gave negative results to all cultures. Lung biopsy showed alveolitis but no micro-organisms were found. The pulmonary symptoms disappeared spontaneously but the fever persisted. In the autumn of 1981 he developed diarrhoea and anal ulcers. *Clostridium difficile* was cultured twice in the faeces and was treated with oral vancomycin on both occasions. The diarrhoea stopped but the anal ulcers persisted. Attempts to identify a causal organism, including culture for herpes simplex virus, were unsuccessful. A therapeutic trial with the immunostimulant Bestatin (Nippon Kayaku Co, Japan) did not alter his clinical condition or appreciably improve the immunological findings.

Case 4—A 31-year-old homosexual man was referred in December 1981 with lymphadenopathy and fever. He had a 12-month history of fatigue, weight loss, pain on swallowing, and recurrent anal ulcers. He had not been to the USA and denied using nitrites or other drugs. He lived with another homosexual man who had been to the USA and used nitrites regularly. On examination he had generalised lymphadenopathy, splenomegaly, and oral thrush. Histological examination of a lymph node from the axillary region showed non-specific "reactive alterations." The oral thrush was treated with mycostatin. After one month of observation he still had fever, but microbiological examination gave negative results.

Discussion

Four previously healthy Danish homosexual men had severe acquired immunodeficiency. In one patient immunological investigations were not performed but the clinical diagnosis of Kaposi's sarcoma and opportunistic infection suggests that he too must have been immune deficient. Three of the cases were the first to be reported in patients who had not previously visited the USA. This indicates that the disease can be acquired outside the USA. All four patients, however, had had sexual contact with homosexual men who had visited or lived in the USA. This is consistent with, but not proof of, an infectious aetiology. Two of the cases (cases 1 and 3) appear to be the first to be reported in patients with known sexual contact. The manifestations of the syndrome were different in these two patients: one developed Kaposi's sarcoma and a fatal *Pneumocystis carinii* pneumonia; the other had chronic anal ulceration and continuous fever. Thus, immunodeficiency may be the common pathogenetic pathway responsible for the different clinical manifestations in these patients.

The immunological studies showed severe defects in cellular immunity with a reduction of the T lymphocyte helper subsets, reduced proliferative response, a decreased natural killer cell activity, and impaired monocyte function. These findings agree with and extend other reports.⁶⁻⁸ The finding of spontaneous leucocyte migration inhibitory factor production, absent leucocyte interferon production (IFN- α), and (in one patient) decreased 5' nucleotidase activity is of interest, since this has also been reported in association with decreased cellular immunity in patients with mononucleosis due to the Epstein-Barr virus or cytomegalovirus infection (unpublished observations).^{21, 22} The

aetiology of the immune deficiency is at present unknown. Several reports have suggested that cytomegalovirus may be the causal agent but final proof is lacking.⁹ Amyl and butyl nitrite sniffing have also been suggested²³; however, one of our patients did not sniff nitrites. Carefully conducted epidemiological investigations may lead to a better understanding of the environmental factors responsible for this new syndrome. The present report draws the attention of European doctors to the syndrome of severe acquired immunodeficiency in homosexual men.

We thank J M Rhodes and J Bennedsen, National Serum Institute, who performed the monocyte studies.
