Cervical cytology in the Vale of Trent faculty of the Royal College of General Practitioners, 1985-8

Andrew Wilson

Abstract

Objective—To assess changes in the organisation and performance of cervical cytology programmes in the practices of members of the Vale of Trent faculty of the Royal College of General Practitioners.

Design—Retrospective audits completed in 1985 and 1988 by general practitioners on a sequential sample of 100 records of women aged 35-64 in their practice.

Setting—General practices in which one or more partners were members or associates of the Vale of Trent faculty of the college, of which 76 participated in the first audit and 55 (82% of 67 eligible practices) in the second.

Subjects—Sequential samples of 100 women born between 1 January 1920 and 31 December 1949 (first audit) and between 1 January 1923 and 31 December 1952 (second audit) whose surnames began with P or B respectively.

Main outcome measures—Percentage of women in each practice with a record of cervical cytology performed in the previous five years and percentage with no recorded smear.

Results—Of the 76 practices completing the audit in 1985, 55 (82% of those eligible) repeated the exercise in 1988. Performance was not significantly different in practices that did and did not respond. The median percentage of women who had had a smear in the previous five years was 49% and 69% in 1985 and 1988 respectively ($p < 0.001$) and that of women with no record of a cervical smear was 28% and 16% respectively ($p < 0.001$). All but six practices showed improvement in both outcome measures. In both audits an active call system was associated with a significantly increased performance ($p < 0.05$). In nine practices (16%) 80% or more of the samples of women had had a smear in the previous five years.

Conclusion—Organisation and performance of practices audited improved between 1985 and 1988. Although this might result from participation in the first audit, it probably represents a more general trend within primary care.

Action—Between the two audits more practices (87% v 67%) had developed a policy on screening, and this was more likely to include the aim of performing regular smears on all sexually active women (98% v 80%).

Introduction

Cervical cancer was responsible for the deaths of 2004 women in England and Wales in 1986,¹ most of which might have been prevented by achieving high rates of coverage in a coordinated cervical cytology programme.² Participation by general practitioners is an essential feature of any such programme, but a

recent national survey showed that only 43% of general practitioners operated a screening system that could identify and call previously untested women.³ The rate of coverage of a programme is the crucial determinant of its success,⁴ although these rates are difficult to determine as routinely published data on cytology are presented as numbers of smears rather than number of women. The government has recently proposed a target of 80% coverage for women who have had a smear within the previous five years, excluding those who have had a hysterectomy.⁵ Participation in peer group audit improves general practitioners performance, at least for those directly involved.^{6,7} The Royal College of General Practitioners has proposed peer group audit as a major route to higher standards, and local faculties have been encouraged to stimulate such activity.⁸

I describe one initiative in which members of the college were invited to audit the organisation and performance of their cervical cytology programmes. The audit was repeated three years later. The aim of these audits was to detect any features of the programmes associated with high performance and to report changes over the three years.

Subjects and methods

In spring of 1985 members of the Vale of Trent faculty of the Royal College of General Practitioners were invited to take part in an audit of cervical cytology.⁹ They were asked about their policy on cervical smears and requested to audit their performance by drawing a sequential sample of 100 women born between 1 January 1920 and 31 December 1949 from their records, starting with records filed under the letter P. Practices in which more than one doctor received the questionnaire were asked to submit only one audit. The audit was performed in 76 practices, representing 101 members (42% response rate). The performance measures were the number of women in the sample who had no record of a smear and the number who had had a smear in the previous five years. Respondents were sent their own results, aggregate results of the audit, and their order of rank.

In spring 1988 a second audit was planned. Of the 76 doctors who had performed the first audit, 69 were thought still to be in post and were invited to repeat their audit, using an identical method, but this time selecting 100 women born between 1 January 1923 and 31 December 1952, starting from the letter B in their records. After the initial posting it was realised that one doctor had moved and another had retired, reducing the denominator to 67 practices. The results of the second audit were compared with those of the first with non-parametric tests.

Results

In the first audit the median percentage of women having a smear within the previous five years was 49% and that of women who had no record of a smear was 27%. Of all the variables measured, only the presence of an active call system was associated with improved performance. One practice achieved the target of 80% of women having a smear within five years.

Fifty five practices (82%) completed the second audit. Responders and non-responders compared in the first audit showed no significant difference in performance. Table I shows the policy changes in these practices over the three year period. Practices were more likely to aim at taking smears from all sexually active women, to increase the frequency of targeting younger women, and to take a repeat smear one year after a first normal smear. The number of practices performing the last routine smear at age 65 increased. Whether or not the women were taking the pill was less likely to influence the frequency of smears. More practices (87% *v* 69%) had established a policy for cervical cytology, and the number of practices in which most smears were performed by the practice nurse increased, from 24% to 36%. Table II shows the changes in call and recall systems over the same period. The number of practices using practice based systems increased, and the number using computers increased more than threefold. Table III shows the differences in performance between the two audits. With both outcome measures performance was significantly increased, the median percentage of women with no record of a smear decreasing by 11% and that of women having a smear within five years increasing by a fifth. All but six practices showed an increased performance with both measures. Nine practices (16%) reached a 80% coverage or more for the sample who had had a smear within the previous five years.

Previous studies have suggested that about 6% of women are ineligible for a cytology programme because of hysterectomy.¹⁰ Assuming that in this study such women did not have a smear unnecessarily, the adjusted median percentage coverage over five years was 100/94, 1.06 times higher than that reported—that is, 73% at

TABLE III—Changes in coverage of cervical cytology in 55 practices between 1985 and 1988

	Outcome measure	
	No record of smear	Smear within past five years
Median (range) percentage in each practice:		
First audit (1985)	28 (6-47)	49 (27-80)
Second audit (1988)	16 (0-35)	69 (37-99)
No (%) of practices:		
With improved performance	49 (89)*	52 (95)*
With reduced performance	4 (7)	3 (5)
With no change in performance	2 (4)	0

**p* < 0.001 (Wilcoxon's matched pairs signed ranks test).

TABLE IV—Performance of 55 practices according to presence of call or recall system (median percentage values)

	Outcome measure	
	No record of smear	Smear within past five years
Call system (n=30)	14.0	70.5
No call system (n=25)	17.0	62.0*
Recall system (n=46)	14.5	69.0
No recall system (n=9)	17.0	62.0

**p* < 0.05 (Mann-Whitney U test).

ferent. As in the first audit only the presence of a call system was associated with increased coverage (table IV).

Discussion

This study shows a willingness among members of the college to take part in audit. It is encouraging that the 82% response to the second audit was not related to performance in the first. There is a danger in giving too much weight to results from individual practices, especially their order of rank as with such small numbers sampling error is high. For example, the 95% confidence interval of a result of 57 out of 100 women having had a smear within five years is 47-67%. In the second audit the rank for these would be 53rd and 31st respectively. In aggregate, however, the study disclosed substantial changes in organisation and performance between 1985 and 1988. In the second audit there was more agreement among practices, and this consensus was close to the policy of the district health authority. The results showed a pronounced improvement in performance, although without a control group of practices it is impossible to say whether this was a result of taking part in the first audit or reflection of more widespread changes in general practice. The limited impact of audit on general practitioners not directly participating in organising audit⁷ suggests that changes in general practice are the more likely explanation.

In this audit one aim was to maximise participation by making the task simple. This entailed some compromise of scientific rigour, particularly in choosing a small non-random sample from each practice. Information was not sought on women ineligible for smears or women declining the offer, proportions that might vary among practices. Although these considerations would be vital if performance was being measured for contractual reasons, they do not detract from the educational aim of the exercise, which was to stimulate interest and activity in cervical screening and to encourage practices to look at their own performance in more detail. It is highly implausible that the improved performance in the second audit resulted from bias owing to the alphabetical source of the sample.

Although the practices taking part are almost certainly not representative of cervical cytology screening

TABLE I—Changes in practice and policy towards cervical cytology in 55 practices in Vale of Trent faculty, 1985-8. Figures are numbers (percentages)

	First audit (1985)	Second audit (1988)
Frequency of smear for women aged 35-44		
Three yearly	17 (31)	35 (64)
Five yearly	35 (64)	18 (33)
Frequency of smear in women aged 46-64 years:		
Three yearly	8 (15)	13 (25)
Five yearly	43 (78)	40 (73)
Aim at repeating first normal smear after 12 months	25 (45)	35 (64)
Age last smear taken (years):		
60	12 (22)	6 (11)
65	25 (45)	41 (75)
70	11 (20)	6 (11)
Death	6 (11)	1 (2)
Practice policy established for cervical cytology	38 (69)	48 (78)
Practice nurse performs most smears	13 (24)	20 (36)

TABLE II—Changes in call and recall systems in 55 practices in Vale of Trent faculty, 1985-8. Figures are numbers (percentages)

	First audit	Second audit
Call system		
Manual only	24 (44)	20 (36)
Computer	2 (4)	10 (18)
None	29 (53)	25 (45)
Recall system		
Manual only	38 (69)	33 (60)
Computer	4 (7)	13 (24)
None	13 (24)	9 (16)

the second audit. Adjusting the 80% target using this assumption results in a revised target of 80/1.06, 75% of a population, including women who have had a hysterectomy; in the second audit 16 practices (29%) achieved this target. The lower target suggested by the government is half of eligible women,⁵ which, by the above calculation, is equivalent to about 47% of the total age group; in the second audit 53 practices (96%) achieved this.

The results of the second audit were analysed to elucidate any association between organisation and performance. Practices in which most smears were taken by a practice nurse and those in which most were performed by the doctor were not significantly dif-

locally or nationally, the finding that within the sample a call system was associated with improved performance replicates other studies, which found that unstructured case finding failed to produce high rates.^{11 12} Because of the issues of method discussed earlier the estimate of practices reaching the target of 80% coverage (28%) is crude. However, this result from highly motivated practices suggests that to be effective the target will have to be seen as an inducement to higher performance rather than a reward for achieving it. Further studies on representative practices are needed to predict whether the target will act as a positive or negative incentive.

In future, outside agencies will provide general practitioners with data about their performance, including that on rates of cervical cytology. Such unsolicited feedback has not proved to be effective in changing behaviour,¹³ although it may be necessary in terms of accountability or for contractual reasons¹⁴; there will remain a place for the type of voluntary, locally organised exercise described here.

This study would not have been possible without the cooperation and help of Janet Bailey, administrative secretary for the Vale of Trent faculty.

Audit in person

Problem solving with audit in general practice

Richard Baker

Introduction

The purpose of medical audit is to improve the quality of care. If badly executed or used for any other purpose audit may waste time and resources that should be used in caring for patients. Whatever we may think of the other proposals in the white paper¹ the new arrangements for audit in general practice offer the profession an opportunity to introduce effective audit that will substantially improve the quality of care. The difficulty is to ensure that audit in practices or organised by medical audit advisory groups is effective in improving care and not wasteful of resources or demoralising to the participants. Audit should therefore be subjected to the same degree of critical evaluation as any other innovations in medicine, such as new treatments or forms of investigation; it has the same potential as these more traditional medical activities to cause harm as well as benefit. I will draw on the experience of some of the successful and unsuccessful audits carried out in my own practice to show why some audits lead to improvements in care and others do not.

Problem solving with audit

The most common reason for failure of audit to improve the quality of care is that the findings do not cause changes in day to day clinical practice. Deficiencies are ignored, either because they are seen as unimportant or because the changes required seem so considerable as to be impracticable. Using audit to solve problems is one way to avoid this difficulty; it is undertaken only when a problem is suspected, which the practice wishes to correct. If audit is to be effective the participants should be the practice team or some of its members—it is the practice that has the problem, and its members are usually the only people who can put it right.

Problems in providing care may be identified in

various ways. There cannot be many general practitioners who are not aware of most of the strengths and weaknesses of the practices in which they work. For example, patients may complain about how difficult it is to speak to their doctor on the telephone or to arrange for repeat prescriptions. The receptionists or practice nurses may more often be the recipients of this type of complaint than the doctors themselves. There are other ways to spot problems. A potentially avoidable important event such as the late diagnosis of appendicitis may indicate a problem of practice management or medical skill that needs investigating; the information from prescribing analysis and cost data may show excessive prescribing of antibiotics; or a training practice inspection may disclose disorganised records. If the practice examines the evidence from such sources and concludes that a problem exists then audit provides one solution. Some types of audit can disclose deficiencies in care, but categorising those deficiencies as problems and then dealing with them demands a different approach. Problems can be thought of as deficiencies that those in the practice think are so important that corrective action must be taken. Some examples may help explain the difference.

Successful audits

Audit 1—The problem: doctors and staff reported to the practice meeting that patients complained how long they had to wait for routine appointments (urgent appointments are available on the same day). At the first data collection the receptionists kept a record of the waiting interval in days regularly over three months. The average wait for an appointment with the patient's chosen doctor was 3.7 days. The solution: we agreed to aim at around three days as a target and introduced a new system offering more and longer appointments. At the second data collection the
