A systematic review of the effects of screening for colorectal cancer using the faecal occult blood test, Hemoccult

Bernie Towler, Les Irwig, Paul Glasziou, Jan Kewenter, David Weller, Chris Silagy

Abstract

Objective: To review effectiveness of screening for colorectal cancer with faecal occult blood test, Hemoccult, and to consider benefits and harms of screening.

Design: Systematic review of trials of Hemoccult screening, with meta-analysis of results from the randomised controlled trials.

Subjects: Four randomised controlled trials and two non-randomised trials of about 330 000 and 113 000 people respectively aged ≥ 40 years in five countries.

Main outcome measures: Meta-analysis of effects of screening on mortality from colorectal cancer.

Results: Quality of trial design was generally high, and screening resulted in a favourable shift in the stage distribution of colorectal cancers in the screening groups. Meta-analysis of mortality results from the four randomised controlled trials showed that those allocated to screening had a reduction in mortality from colorectal cancer of 16% (relative risk 0.84 (95% confidence interval 0.77 to 0.93)). When adjusted for attendance for screening, this reduction was 23% (relative risk 0.77 (0.57 to 0.89)) for people actually screened. If a biennial Hemoccult screening programme were offered to 10 000 people and about two thirds attended for at least one Hemoccult test, 8.5 (3.6 to 13.5) deaths from colorectal cancer would be prevented over a period of 10 years.

Conclusion: Although benefits of screening are likely to outweigh harms for populations at high risk of colorectal cancer, more information is needed about the harmful effects of screening, the community's responses to screening, and costs of screening for different healthcare systems before widespread screening can be recommended.

Introduction

Colorectal cancer is a leading cause of illness and death in the Western world. In Australia, the United Kingdom, and the United States it is the commonest cancer in women after breast cancer (age standardised incidence 22-33 per 100 000) and in men after prostate and lung cancer (age standardised incidence 31-47 per 100 000).^{1 2} Just under half of all people affected will die from their disease.^{1 2} The human and financial costs of this disease have prompted considerable research efforts to evaluate the ability of screening

tests to detect the cancer at an early, curable stage. Tests that have been considered for screening include faecal occult blood tests, sigmoidoscopy, and colonoscopy.

We have reviewed the evidence about the ability of screening with the faecal occult blood test Hemoccult to reduce mortality from colorectal cancer. Since follow up in Hemoccult screening trials has not been sufficiently long to clarify the effect of detecting and removing adenomas on mortality, our results reflect the effect of detecting early colorectal cancer on mortality. As well as evaluating the effectiveness of screening, we also considered its benefits and harms. If screening is effective, for which populations would screening be likely to be of net benefit, given the potential harms? Weighing the benefits and harms of screening helps to define health policy and future research needs. We reviewed the information from the screening trials about physical harm associated with follow up colonoscopy or sigmoidoscopy. Other harmful screening effects include disruption to lifestyle, the stress and discomfort of testing and further investigations, and the anxiety caused by false positive tests.³ This review will also be published and maintained on *The Cochrane Library*, an electronic publication of the Cochrane Collaboration (Oxford: Update Software).

Methods

We conducted a comprehensive search of the health literature for all controlled trials of screening for colorectal cancer by means of faecal occult blood tests. The search included correspondence with trialists for unpublished data and clarification of published results. Details of this search are available on request. The trials were independently assessed for their quality by BT and PG using criteria recommended by the Cochrane Collaboration.⁴ Disagreements about quality were resolved by discussion.

Data from the trials were independently extracted by BT and LI and analysed using Meta-analyst version 0.991.⁵ We performed the data analysis on an "intention to screen" basis—using the groups that subjects were randomised to whether or not they were ever screened. To determine the size of the effect of screening on mortality from colorectal cancer, we estimated relative risks and risk differences, firstly for each trial and then overall, using fixed and random effects models and then used the χ^2 test for heterogeneity of effects.^{5 6}

Analysis by intention to screen underestimates the effect that would be seen in those who actually attended screening. Hence, as a secondary analysis, we adjusted for attendance for screening in individual trials using a previously published method.⁷ Essentially, this involves dividing the intention to screen effect (relative risk reduction) by the proportion attending.

Results

Trial characteristics

We identified four randomised controlled trials⁸⁻¹¹ and two non-randomised controlled trials^{12, 13} that evaluated the effectiveness of screening with the faecal occult blood test Hemocult. The randomised trials involved about 330 000 people in Denmark, England, Sweden, and the United States, and the non-randomised trials involved about 113 000 people in France and the United States. Table 1 shows the characteristics of the trials. Most trials commenced in the mid-1970s or early 1980s and involve annual or biennial Hemocult screening.⁸⁻¹¹ The non-randomised New York trial evaluated Hemocult in addition to sigmoidoscopy, which was offered to all trial participants.¹²

The Funen, Nottingham, and Gothenburg trials randomly allocated individuals or households identified from general practitioner records or population registers to invitation to screening with Hemocult or to control groups (table 2). The Minnesota and New York trials allocated people who had agreed to participate in the trials ("volunteers") to screening or control groups, while the Burgundy trial, which started in 1988, non-randomly allocated groups from defined areas to screening or control groups (table 2). The number of groups allocated was not reported. The age of participants varied from trial to trial, with all being at least 40 years old (table 1). Follow up continues in at least four of the trials (table 1).

In all six trials participants were encouraged to restrict their diet or medications around the time of the Hemocult tests in order to reduce the possibility of a false positive result. The nature of these restrictions varied from trial to trial. For most trials, the Hemocult stool slides were not rehydrated, resulting in a low test positivity rate (0.8%-2.4%) and a higher positive predictive value for colorectal cancer (5.6%-17.7%) compared with the rehydrated test, for which the test positivity rate was 4.8%-9.8% and the positive predictive value was 2.2%-4.2% (table 1).

In all the trials, those subjects with a positive Hemocult test were referred for further investigation, mainly colonoscopy or sigmoidoscopy with double contrast barium enema. Colorectal neoplasms (cancers and adenomas) found on further investigation were removed. In the Minnesota trial 38% of the group offered annual screening and 28% of the group offered biennial screening had at least one colonoscopy.⁸ Some 2%-3% of the screening group in the Nottingham and Funen trials^{9, 10} and about 6% in the Gothenburg trial¹⁴ had at least one endoscopy (colonoscopy or sigmoidoscopy). About 4% of the screening group in the New York study were investigated for a positive Hemocult test, most of these having colonoscopy.¹²

Trial design quality

Randomisation was performed appropriately for four of the trials, resulting in comparable study groups (table 2).^{8-11, 15} The New York study was non-randomised, and the study groups were not comparable: the numbers recruited to the groups were not proportional to the months of recruitment, and there were differences between the groups in age, sex, and symptoms at enrolment, suggesting bias in the allocation of subjects to the study groups (table 2). For example, only 23% of the subjects in the subgroup of regular attenders to the clinic were controls, although about a third of the months were allocated for recruit-

ment of controls to this subgroup. In the non-randomised Burgundy study all residents of certain towns and districts in the Saone et Loire department were invited to participate in screening. Controls were residents of areas of similar size from a neighbouring department. The selection process of towns and districts was not explained. Data about the comparability of the study groups are not yet available for the Burgundy study.

Mortality analyses were by intention to screen for the Minnesota, Nottingham, and Funen studies (table 2). In the Gothenburg trial 197 subjects were excluded from the screening group: these people could not be located or had died between randomisation and screening.¹⁶ It is not clear if there were exclusions in the New York study. Follow up was complete or high for all studies (table 2). Blinded standardised outcome assessment was performed for the four trials with published mortality findings (table 2).

Intermediate outcome measures

The estimated sensitivity of the Hemocult test for colorectal cancer varied from 46% (unhydrated Hemocult in the Funen trial) to 92% (rehydrated Hemocult in the Minnesota trial) (table 3). Sensitivity was defined as the proportion of all colorectal cancers that were detected by screening, with all colorectal cancers being the sum of screen detected cancers (true positives) and interval cancers within one or two years of screening (false negatives) (table 3).

The percentage of people allocated to the screening group who completed at least one Hemocult test ranged from 60% in the Nottingham trial to 90% in the Minnesota trial (table 1). Attendance for screening was higher in the American trials than in the European trials. Hemocult screening continued to be offered to all participants in most trials, regardless of prior attendance (table 1).

Because screening results in earlier diagnosis of cancer, we would expect an excess of colorectal cancers initially in the screen groups. This was the case for four of the five trials in which these data were available (table 3).¹²⁻¹⁸ It is unclear why this did not happen in the Min-

nesota trial.¹⁹ It is possible that fewer cancers were detected in the screening group by chance, and this may then also be associated with an underestimation of mortality from colorectal cancer in the screening group.

In the screening groups, removal of adenomas detected at investigation of a positive Hemocult test might affect later incidence of cancer. However, cumulative rates of colorectal cancer after 8-13 years of follow up were similar in screening and control groups in all of the trials (table 3).

Reported numbers of colorectal cancers varied at different points in the Minnesota paper.⁸ The paper's table 4 reported the numbers of cancers in the annual screening, biennial screening, and control groups as 323, 323, and 356 respectively, whereas the paper's table 5 and figure 3 reported these numbers as 354, 368, and 394 respectively. The first set of numbers represent the numbers of colorectal cancers diagnosed through 13 years of follow up, as data were available for all study participants at 13 years; additional cancers diagnosed until 17 years of follow up were included for cancer staging and survival analyses (Mandel, personal communication).

We would also expect that screening would result in a favourable shift in the stage distribution of colorectal cancers. All five trials reported that, of the colorectal cancers detected, a higher proportion were early stage (Dukes's type A) and a lower proportion late stage (Dukes's type D or type C and D) in the screening groups than in the control groups (table 3). This favourable shift in cancer staging occurred even though only 25%-50% of cancers in the screening groups were actually detected by screening (table 3).

Mortality

Mortalities were published for the Minnesota, Nottingham, Funen, and New York trials (table 3). The Minnesota trial reported a 33% reduction in mortality from colorectal cancer with annual screening (relative risk 0.67 (95% confidence interval 0.51 to 0.89)) and a 5% reduction with biennial screening (relative risk 0.95 (0.74 to 1.23)). The Nottingham and Funen studies reported reductions in mortality with biennial screen-

CRC=Colorectal cancer.

ing of 14% (relative risk 0.86 (0.74 to 0.99)) and 18% (0.82 (0.68 to 0.99)) respectively. Results from the New York study were reported for two subgroups defined by whether the subjects had attended the clinic previously (regular attenders) or were attending for the first time. After nine years of follow up, there was a 37% reduction in mortality with annual screening among those attending for the first time (relative risk 0.63 (0.31 to 1.27)) but an 18% increase in mortality with annual screening among the regular attenders (relative risk 1.18 (0.48 to 2.88)).

The Gothenburg and Burgundy trials have still to publish mortality findings. Unpublished results from the Gothenburg trial indicate that, after eight years of follow up, there was a 12% reduction in mortality with biennial screening (relative risk 0.88 (0.69 to 1.12)) (table 3).

Adverse events relating to colonoscopy or sigmoidoscopy were reported for only the Minnesota and Gothenburg trials. In the Minnesota trial four perforations and 11 cases of serious bleeding resulted from 12 246 colonoscopies (12 complications per 10 000 colonoscopies). The Gothenburg trialists reported that 0.3% of 2 298 endoscopies (colonoscopies and sigmoidoscopies) were complicated by perforation or haemorrhage (30 complications per 10 000 endoscopies).

Meta-analysis

The Minnesota trial found a 33% reduction in mortality from colorectal cancer with annual screening and a 5% reduction with biennial screening. We combined these risks of death for the two screening groups for reasons discussed later, and comparison of this value with the risk in the control group suggests an overall reduction of 19% in the risk of death with screening (relative risk 0.81 (0.65 to 1.02)) (table 3).

The mortality results from the four randomised controlled trials did not seem to be heterogeneous, and formal testing for heterogeneity confirmed this (χ^2 test for heterogeneity 0.37, df = 4, $P > 0.5$). We combined the mortality results from these four trials to obtain a summary measure of the effectiveness of screening for colorectal cancer with Hemoccult (figure). Meta-analysis with a random effects model showed that screening resulted in a significant overall reduction in mortality from colorectal cancer of 16% (relative risk 0.84 (0.77 to 0.93)). With a fixed effects model, the summary relative risk was unchanged, and the 95% confidence interval decreased by 0.01. When we adjusted the relative risk for attendance for screening in individual studies (using the data from table 3 on the percentage who completed at least one screen) the

Effects of screening with Hemoccult on mortality from colorectal cancer (random effects model)

overall relative reduction in mortality was 23% (relative risk 0.77 (0.57 to 0.89)) for those screened.

Including the results from the non-randomised New York study in the meta-analysis made no substantive difference to the summary result (relative risk 0.84 (0.77 to 0.92)) with both fixed or random effects models.

The meta-analysis shows more variability in the risk difference than in the relative risk (figure). As the relative risk was relatively constant, the variability in the risk difference is a reflection of the variation in the background risk of death from colorectal cancer in the various study populations—ranging from 40 deaths per 10 000 population in the Gothenburg study to 80 deaths per 10 000 in the Funen study. Overall, if 10 000 people were offered screening, 8.5 (95% confidence interval 3.6 to 13.5) deaths from colorectal cancer would be prevented over 10 years. To state this another way, the number needed to screen in order to prevent one death from colorectal cancer over 10 years is 1173 (741 to 2807) with either fixed or random effects models.

Discussion

The combined evidence to date from randomised controlled trials of Hemoccult screening suggests that screening reduces mortality from colorectal cancer. The point estimate is 16%, but the reduction may be as great as 23% or as little as 7%. Mortality results are not yet published for the Gothenburg and Burgundy trials, although results from Gothenburg have been included in this meta-analysis and the Burgundy study is not randomised. The reduction in mortality associated with screening was consistent across the five trials with mortality results even though they varied in the selection and age of their study populations, screening intervals, conditions of Hemoccult testing and slide processing, length of follow up, and attendance for screening.

The results of the Minnesota trial seem paradoxical: a 33% reduction in mortality from colorectal

cancer with annual screening, but a 5% reduction with biennial screening. Screening twice as often can, at best, double the relative reduction in mortality, but the effect is usually much less. If the benefit of annual screening was more than double that of biennial screening, it would suggest that screening half the population every year would have a greater impact than screening all the population every two years. To consider this another way, even if the sojourn time of cancers is less than a year, a screen every two years must pick up the cancers that arose in the past year (and hence would be picked up by annual screening). So the effect of biennial screening must be at least half that of annual screening, and will be more than half to the extent that the distribution of sojourn times exceeds a year. Thus, we believe that the difference in mortality reduction between the annual and biennial screen groups in the Minnesota trial is partly due to the play of chance. This play of chance may have occurred at randomisation, since the screening groups did not show the expected higher initial rate of colorectal cancers as a result of screening.

Implications of results

Who would be likely to benefit from screening? Assuming a constant reduction in relative risk, the benefit of screening is greatest in populations at greatest risk of death from colorectal cancer while the harmful effects of screening are likely to be independent of this risk.²⁰ Indeed, the screening trials showed increasing benefit of screening with increasing population risk of death from colorectal cancer. The reduction in the relative risk of death with screening needs to be interpreted for its benefit in the overall population, in which there are differing baseline risks of colorectal cancer. In addition to people from families with a known genetic predisposition for colorectal cancer (including familial adenomatous polyposis and hereditary non-polyposis colorectal cancer) groups at increased risk of colorectal

Key messages

- We conducted a systematic review of trials of screening for colorectal cancer with faecal occult blood test, Hemoccult
- Meta-analysis of results from the four randomised controlled trials showed that screening reduced mortality from colorectal cancer by 16% for those allocated to screening and by 23% for those who were actually screened
- A biennial Hemoccult screening programme offered to 10 000 people aged ≥ 40 years, of whom about two thirds attended for at least one test, would prevent 8.5 deaths from colorectal cancer over 10 years
- Although benefits of screening are likely to outweigh harms for populations at high risk of colorectal cancer, we need more information about the harmful effects of screening, the community's responses to screening, and costs of screening for different healthcare systems before widespread screening can be recommended

cancer (and thus death from cancer) include those with a family history of colorectal cancer of no known genetic basis.²¹⁻²⁴ The risk of colorectal cancer also increases markedly with age.¹

The expected benefit of screening can be estimated for different populations to guide health policy decisions about who should be offered screening. For example, in New South Wales, Australia, in 1991 the cumulative 10 year mortality from colorectal cancer in men in their 40s, 50s, and 60s were 9.6, 40, and 98 respectively per 10 000 population.¹ If offering screening reduced this mortality by 16% the reduction in deaths over the following 10 years for each of these age groups would be 1.5, 6.4, and 15.6 respectively per 10 000 invited. This somewhat overestimates the benefit, as some of the mortality relates to cancers diagnosed before that decade. However, it is also an underestimate for those who actually attend for screening. If we use the mortality reduction of 23% estimated for those actually screened, the reduction in deaths over 10 years would be 2.2, 9.2, and 22.5 respectively per 10 000.

Based on the combined results of the four randomised controlled trials of Hemoccult screening, we estimate that, if a biennial screening programme were offered to 10 000 people, of whom about two thirds attended for at least one Hemoccult test, 8.5 colorectal cancer deaths would be prevented over about 10 years. The number of colonoscopies or sigmoidoscopies performed among the screening groups to achieve this reduction in mortality could range from 20 to 800 per life prolonged, according to the results of the screening trials. If we consider the harm of screening, the results from the Minnesota trial indicate that a biennial screening programme would result in 2800 participants having at least one colonoscopy, with there being 3.4 complications (perforation or haemorrhage) associated with these colonoscopies. The results from the Gothenburg trial, however, indicate that about 600 participants would need at least one sigmoidoscopy and double contrast barium enema, resulting in 1.8 perforations or haemorrhages. Colonoscopy rates were lower for the trials in which the Hemoccult stool slides were not rehydrated, but information about complications was not reported.

An important issue is the accuracy of the screening test. Under trial conditions, which are likely to be supe-

rior to those of a screening programme, Hemoccult had a low positive predictive value for cancer, so that over 80% of positive tests were false (table 3). All these people still required investigation, with its associated stress and risk of bowel perforation and haemorrhage. Since the trials were initiated, other faecal occult blood tests have emerged that may be more accurate.^{25 26} More specific tests will potentially have a major impact on the ratio of benefit to harm of a screening programme, as fewer false positive tests will mean fewer colonoscopies, with their associated harms, for the same benefit in terms of reduced mortality from colorectal cancer. It is also worth noting that among the people with a false positive test for cancer are some with colorectal adenomas. Further analysis of trial data during follow up should clarify whether the detection and removal of adenomas alters the subsequent incidence of cancer, and thus mortality.

Conclusions

The estimate of the reduction in mortality associated with screening for colorectal cancer with Hemoccult is now well quantified, and the confidence intervals are narrow enough to allow the conclusion that screening is likely to be of net benefit for some population groups. Other benefits of screening that we have not explored include a possible reduction in incidence of colorectal cancer through detection and removal of colorectal adenomas and, potentially, less invasive surgery through treatment of early colorectal cancers.

However, there are still some important issues to be answered. There is insufficient information from the trials about the harmful physical and psychosocial effects of screening. What does the community think and feel about screening? How do we best inform high risk populations about the pros and cons of screening, and would these people participate in screening? Can the necessary quality of screening and follow up be achieved outside trials, and would expenditure on screening constitute a sound use of resources given local priorities in health care? These questions require further evaluation by researchers for different health-care systems.

Changes in left ventricular structure and function in patients with white coat hypertension: cross sectional survey

Michael W Muscholl, Hans-W Hense, Ulrich Bröckel, Angela Döring, Günter A J Riegger, Heribert Schunkert

Abstract

Objectives: To assess the relation between white coat hypertension and alterations of left ventricular structure and function.

Design: Cross sectional survey.

Setting: Augsburg, Germany.

Subjects: 1677 subjects, aged 25 to 74 years, who participated in an echocardiographic substudy of the monitoring of trends and determinants in cardiovascular disease Augsburg study during 1994-5.

Outcome measures: Blood pressure measurements and M mode, two dimensional, and Doppler echocardiography. After at least 30 minutes' rest blood pressure was measured three times by a technician, and once by a physician after echocardiography. Subjects were classified as normotensive (technician < 140/90 mm Hg, physician < 160/95 mm Hg; n = 849), white coat hypertensive (technician < 140/90 mm Hg, physician ≥ 160/95 mm Hg; n = 160), mildly hypertensive (technician ≥ 140/90 mm Hg, physician < 160/95 mm Hg; n = 129), and sustained hypertensive (taking antihypertensive drugs or blood pressure measured by a technician ≥ 140/90 mm Hg, and physician ≥ 160/95 mm Hg; n = 538).

Results: White coat hypertension was more common in men than women (10.9% versus 8.2% respectively) and positively related to age and body mass index.

After adjustment for these variables, white coat hypertension was associated with an increase in left ventricular mass and an increased prevalence of left ventricular hypertrophy (odds ratio 1.9, 95% confidence interval 1.2 to 3.2; P = 0.009) compared with normotensive patients. The increase in left ventricular mass was secondary to significantly increased septal and posterior wall thicknesses whereas end diastolic diameters were similar in both groups with white coat hypertension or normotension. Additionally, the systolic white coat effect (difference between blood pressures recorded by a technician and physician) was associated with increased left ventricular mass and increased prevalence of left ventricular hypertrophy (P < 0.05 each). Values for systolic left ventricular function (M mode fractional shortening) were above normal in subjects with white coat hypertension whereas diastolic filling and left atrial size were similar to those in normotension.

Conclusion: About 10% of the general population show exaggerated inotropic and blood pressure responses when mildly stressed. This is associated with an increased risk of left ventricular hypertrophy.

Introduction

A physical examination by a physician may cause a rise in the patient's blood pressure. Individuals showing
