affected births, in spite of the increase in the numbers diagnosed prenatally.

We thank Christina Kelekun and Karen Wells for data entry and verification. The heads of the cytogenetic laboratories of England and Wales and the Association of Clinical Cytogeneticists provide continued support and data.

Contributors: EA was the grant holder and director of research and contributed in discussion and to the drafting of the manuscript; she is guarantor for the study. RGI was responsible for the development and efficiency of the coding and data entry for the register from 1989 to 1997. DM was project coordinator and cytogeneticist for the register with responsibility for analysing the data and writing the manuscript.

Funding: The register was initially funded by the Medical

Research Council; since 1994 it has been funded by North and South Thames NHS Research and Development.

Effect of parity, gravidity, previous miscarriage, and age on risk of Down's syndrome: population based study

Annabelle Chan, Kieran A McCaul, Rosemary J Keane, Eric A Haan

The increased risk of Down's syndrome with maternal age underlies the recommendation for older pregnant women to be offered screening by amniocentesis or chorionic villus sampling. Recently Schimmel et al suggested that increased parity was an independent risk factor for Down's syndrome, but their study was not population based and did not include terminations of pregnancy.¹

Using statewide statistics on births and terminations of pregnancy we investigated whether the risk of Down's syndrome is increased independently of maternal age by maternal parity, gravidity, or previous miscarriage.

Subjects, methods, and results

South Australia has around 20 000 births annually. The state collects data on birth defects that include maternal characteristics in both its perinatal and abortion statistics. These statutory collections are complemented by notifications from health professionals to the South Australian Birth Defects Register of defects in children detected within the first 5 years of life and by cytogenetic and necropsy reports. Each case of Down's syndrome included in these collections has been cytogenetically confirmed.

The effects of parity, gravidity, number of previous miscarriages, and mother's age (by single year of age) on risk of having a fetus with Down's syndrome were modelled separately using Poisson regression; then the effects of parity, gravidity, and previous miscarriage were modelled separately after adjustment for the effect of mother's age. Overdispersion was detected in all the Poisson models constructed, and an overdispersion factor was estimated using the square root of Pearson's χ^2 divided by the number of degrees of freedom.² The analysis was performed using PROC GENMOD in SAS.³ Analyses were undertaken for 1986-95 and 1986-90, which was similar to the period of study of Schimmel et al (1981-9) and preceded the gradually increasing use of maternal serum screening for Down's syndrome.

Analysis using births and terminations of pregnancy showed no significant increase in risk for increase in parity or gravidity (table). When only births were analysed for 1986-95, the increased risks with increase in parity ($P < 0.001$) and gravidity ($P < 0.01$) were not significant after adjustment for age ($P = 0.46$ and $P = 0.75$ respectively); similar results were obtained for 1986-90 for increase in parity. The risk was not increased with the number of previous miscarriages, but the increase in risk with age was constant ($P < 0.001$).

Comment

Schimmel et al studied live births alone among women of high parity attending one hospital. Their analysis of maternal age by five year age groups might have contributed to spurious results through truncation.¹

The low risk found in women of low parity may have resulted from the inadvertent exclusion of women of low parity who had had Down's syndrome diagnosed in their fetus prenatally elsewhere and spontaneously miscarried or terminated the pregnancy.¹ Another Australian population based study found that older pregnant women who had had three or more previous births were less likely than those of lower parity to undergo amniocentesis or chorionic villus sampling, although all were eligible for a medical service rebate.⁴ We found a similar differential use of prenatal diagnosis in univariate analysis among South Australian women who were pregnant in 1991-6 (odds ratio 0.55 (95% confidence interval 0.51 to 0.61)) and also found a similar higher use of these tests among women who had had a previous termination of pregnancy. These and other differences identified may reflect different degrees of knowledge about the availability of tests, concern about the possibility of having a disabled child, or attitudes towards termination of pregnancy.⁴

With the operation of selection factors and increasing use of prenatal diagnosis, risk estimates of Down's

BMJ 1998;317:924-5

Evidence exists of considerable problems with bullying and bullied children in secondary schools. In the largest survey in the United Kingdom to date 10% of pupils reported that they had been bullied "sometimes or more often" during that term, with 4% reporting being bullied "at least once a week."¹ The impact of the introduction of policies on bullying throughout a school seems to be limited.¹ The commonest type of bullying is general name calling, followed by being hit, threatened, or having rumours spread about one.¹ Bullying is thought to be more prevalent among boys and the youngest pupils in a school.²

We are unaware of any study that has examined the mental health problems of children who are being bullied. We assessed self reported anxiety, depression, and self esteem in bullied children and those who were not bullied and in bullies and those who were not bullies.

Subjects, methods, and results

Four questionnaires (the Olweus bully/victim,² the short mood and feelings,³ the revised children's manifest anxiety incorporating a lie scale,⁴ and the Rosenberg self esteem⁵ questionnaires) were anonymously completed by 904 pupils aged 12-17 in years 8-11 in two coeducational secondary schools. School A is a non-selective school in a socially disadvantaged urban area. School B is a rural grant maintained school in an area with a higher than average proportion of high social class households.

Logistic regression models were fitted to the proportions of bullied or bullying children using STATA. Categorical variables were school, school year, and sex. Anxiety, lying, esteem, and depression scores were treated as continuous variables. The table shows the odds ratios of the fitted logistic regression models.
