Prescribed exercise in people with fibromyalgia: parallel group randomised controlled trial

Selwyn C M Richards, David L Scott

Abstract

Objectives To evaluate cardiovascular fitness exercise in people with fibromyalgia.

Design Randomised controlled trial.

Setting Hospital rheumatology outpatients. Group based classes took place at a "healthy living centre."

Participants 132 patients with fibromyalgia.

Interventions Prescribed graded aerobic exercise (active treatment) and relaxation and flexibility (control treatment).

Main outcome measures Participants' self assessment of improvement, tender point count, impact of condition measured by fibromyalgia impact questionnaire, and short form McGill pain questionnaire.

Results Compared with relaxation exercise led to significantly more participants rating themselves as much or very much better at three months: 24/69 (35%) v 12/67 (18%), $P=0.03$. Benefits were maintained or improved at one year follow up when fewer participants in the exercise group fulfilled the criteria for fibromyalgia (31/69 v 44/67, $P=0.01$). People in the exercise group also had greater reductions in tender point counts (4.2 v 2.0, $P=0.02$) and in scores on the fibromyalgia impact questionnaire (4.0 v 0.6, $P=0.07$).

Conclusions Prescribed graded aerobic exercise is a simple, cheap, effective, and potentially widely available treatment for fibromyalgia.

Introduction

Medically unexplained symptoms, especially pain, are common reasons for patients consulting their general practitioner and attending hospital clinics. They have major negative impacts on quality of life. Chronic widespread musculoskeletal pain is a particular problem with a community prevalence of 11-13% in the United Kingdom.^{1 2} Fibromyalgia, the severe end of the spectrum, comprises chronic musculoskeletal pain in association with multiple tender points. Its community prevalence is 1%.³ Fibromyalgia overlaps with chronic fatigue and other medically unexplained syndromes.⁴

Conventional medical treatment of fibromyalgia with analgesics, non-steroidal anti-inflammatory drugs, and antidepressants is relatively ineffective. Prospective observational studies show little improvement over

four to seven years.⁵⁻⁷ Exercise therapy is an alternative approach. Its use reflects the cognitive behaviour model of fibromyalgia in which maladaptive fear of worsening symptoms prevents individuals from being active.⁸⁻¹¹

Several randomised controlled trials of exercise therapy in fibromyalgia have given generally positive results. However they were underpowered, excluded many cases, and lack generalisability because the interventions took place in hospitals and were supervised by highly experienced healthcare professionals.¹²⁻¹⁸ We report a randomised controlled trial that evaluated the prescription of a community based exercise programme in patients with fibromyalgia who were seen in a hospital outpatient rheumatology clinic. Our trial was designed to be inclusive of all cases, widely generalisable, and adequately powered.

Methods

Participants

We included in the study men and women aged 18-70 years who had fibromyalgia according to the criteria of the American College of Rheumatology 1990¹⁹ and were able to give informed consent.

We identified potential participants by hand searching copies of all letters sent from clinics to general practitioners to identify patients diagnosed with fibromyalgia who were attending rheumatology clinics at one teaching hospital between January 1997 and June 1998.

We excluded 29 people in whom an alternative medical diagnosis could explain current symptoms and 22 who were unable to attend classes (10 lived too far away, four were too busy, four were too incapacitated, four had other reasons). Other exclusion criteria were severe pulmonary, cardiovascular, renal, or neurological disease precluding involvement in aerobic exercise and inability to cooperate, but no participants were excluded for these reasons.

Trial interventions

The observer blind parallel group randomised controlled trial evaluated 12 weeks of exercise in 136 participants followed for one year from entry. Participants answered questionnaires and underwent examination before treatment, immediately after treatment (at three months), and at six and 12 months. Participants completed questionnaires before assessment

by a single blinded assessor (SR) who recorded physical outcome measures and remained unaware of the allocation throughout the trial. The local research ethics committee approved the study, and all participants gave informed consent.

Participants were randomly assigned in equal proportion to either graded aerobic exercise or relaxation. An independent researcher not involved in the assessments used a random number table for allocation.

Both groups met in hour long classes of up to 18 individuals twice weekly for 12 weeks. Participants continued their medication at entry. They received standardised advice including an explanation of fibromyalgia and encouragement and were told that the exercise offered through prescription would improve their condition. Each week at the classes all individuals received an information leaflet covering an aspect of their condition. The interventions were carried out by personal trainers blinded to the hypothesis of the trial.

Exercise therapy comprised an individualised aerobic exercise programme, mostly walking on treadmills and cycling on exercise bicycles. Each individual was encouraged to increase the amount of exercise steadily as tolerated. When people first started classes they usually did two periods of exercise per class lasting six minutes. By 12 weeks they were doing two periods of 25 minutes at an intensity that made them sweat slightly while being able to talk comfortably in complete sentences.

Relaxation and flexibility comprised upper and lower limb stretches and relaxation techniques based on the published regimen by Ost.²⁰ As the classes continued more techniques were introduced progressing through progressive muscle relaxation, release only relaxation and visualisation, cue controlled relaxation, and differential relaxation. This occupied the whole one hour class.

Primary outcome measure

Our primary outcome measure was the change in self rated global impression, which is a validated measure of overall change from study onset²¹ previously used in exercise intervention trials in fibromyalgia and chronic fatigue syndrome.^{22–24} We measured change on a 7 point scale ranging from 1 (very much worse) to 7 (very much better). We regarded participants with scores of 6 and 7 as responders and those with other scores or who did not attend classes as non-responders.

Table 1 Details of randomised patients

	Relaxation (n=67)	Exercise (n=69)
Median (interquartile range) age (years)	45 (38–52)	48 (38–56)
Median (interquartile range) duration (years)	4 (3–9)	6.5 (3–10)
Median (interquartile range) education (years)	11 (10–14)	12 (10–14)
Single	33	35
Women	64	62
Currently employed	14	23
Receiving social security benefits	49	40
Taking analgesics	27	27
Taking antidepressants	20	16
Fulfil criteria for chronic fatigue syndrome	48	47
Mean (SD) SF-36 summary z scores*:		
Mental component	–3.9 (1.6)	–3.6 (1.3)
Physical component	–3.9 (1.1)	–3.7 (0.9)

*Compared with means of UK populations.

Outline of flow of patients in study

Secondary outcome measures

To give a tender point count a blinded observer recorded tenderness at the 18 sites specified in the fibromyalgia classification criteria. We used the fibromyalgia impact questionnaire to assess symptoms, disability, and handicap.²⁵ We also used the Chalder fatigue scale to assess physical and mental fatigue in two different constructs,²⁶ the short form McGill pain questionnaire,²⁷ and SF-36.²⁸

Sample size and analysis

The study was powered to detect a 25% difference between the two arms (that is, response rates of 20% in the control arm and 45% in the active treatment arm) when treatment was completed at three months with a significance level of 5% and 80% power. This needed 51 participants in each arm. With allowance for a 30% dropout rate we calculated we would need a final sample size of 132 (66 per arm).

We used Fisher's exact test for comparisons at three months. We classified participants who failed to attend any classes as non-responders and analysed data on an intention to treat basis. We replaced any missing follow up data with the last known value even if this was the baseline value. We used non-parametric methods as data were not normally distributed. We used Mann-Whitney U tests for analyses between groups and Wilcoxon signed rank tests for changes from baseline within groups.

Results

The figure summarises the participants identified, contacted, and enrolled into the trial. We randomised 136 participants, and 108 attended for baseline assessments and at least one class. Table 1 shows baseline assessments of the two groups. The participants were highly disabled (mean summary SF-36 scores >3 SD below normal), and 89 (65%) were receiving benefits. The two groups were comparable for all recorded demographic characteristics. Only 72 (53%) participants attended over one third of the classes.

Intention to treat analysis of the primary outcome

At three months 24/69 (35%) participants randomised to the exercise arm were much better or very much better compared with 12/67 (18%) randomised to the

Table 3 Scores on fibromyalgia impact questionnaire scores in people with fibromyalgia over time according to allocation to exercise or relaxation classes

Time	Mean scores (95% CI)		Mean change between groups (95% CI)	P value
	Relaxation group (n=65)	Exercise group (n=68)		
Baseline	56.6 (53.6 to 59.5)	59.6 (56.6 to 62.5)	NA	NA
3 months	54.7 (51.1 to 58.3)	55.0 (51.7 to 59.1)	1.9 (−2.5 to 6.3)	0.5
6 months	56.4 (53.0 to 59.8)	54.2 (51.1 to 58.4)	4.4 (−0.3 to 9.0)	0.05
1 year	56.0 (52.8 to 59.5)	55.6 (52.4 to 59.9)	2.5 (−2.7 to 7.8)	0.07

NA=not applicable.

relaxation arm (Fisher's test $P=0.032$ for difference). Twelve participants in each group had dropped out by three months, and these were all rated as non-responders. The benefits were maintained at 12 months in 26 (38%) and 15 (22%) participants respectively ($P=0.06$).

Tender point count and criteria for fibromyalgia

In both groups the tender point counts had fallen significantly at three months (table 2). This reduction persisted for 12 months ($P<0.001$, Wilcoxon signed ranks test), though by then the difference between the two groups was greater and favoured the exercise group ($P=0.02$ on Mann-Whitney U test). This fall in tender point counts meant that at 12 months only 75 (55%) of participants still met the diagnostic criteria for fibromyalgia, and significantly fewer of them were in the exercise group (31 v 44 in relaxation group, $P=0.017$ by Fisher's exact test).

Secondary outcome measures

At three months there were no significant changes between the two groups in the results from the fibromyalgia impact questionnaire. However improvement was greater in the exercise arm, and this benefit increased with follow up (table 3). The physical, mental, and total fatigue scores as measured by the Chalder fatigue scale all showed significant falls (between 20–30% of baseline values) in both groups at three months, and this was maintained at 12 months (data not shown). There were no significant differences between groups. The McGill pain scores had fallen significantly at three months in both groups (14% of baseline values with exercise and 6% with relaxation), and this was maintained in the exercise arm at six months (10% of baseline values). There were no significant differences between groups (data not shown). From the SF-36 the physical components summary scores improved in both groups at three months. The mean (SD) scores at baseline were -3.6 (1.3) in the exercise group and -3.3 (1.6) in the relaxation group. There were no significant differences between groups. The mental components summary scores were virtually unchanged.

We did not record any adverse events in either group.

Discussion

Our results show that a three month programme of prescribed graded aerobic fitness exercises significantly benefits participants' global self rating of fibromyalgia. Tender point counts and scores on fibromyalgia impact questionnaires also improved. Some benefits, like the fall in tender point counts, lasted 12 months.

Previous reports have described exercise interventions performed by highly qualified healthcare professionals in selected hospital patients. We excluded only a few people from our pragmatic trial, despite studying severely affected people whose pain and fatigue had lasted several years. Our instructors were personal trainers with no special experience in providing exercise for people with ill health. Our patients attended classes of their own accord and arranged their own transport, and the large class sizes minimised costs. Though people in the relaxation arm attended fewer classes, this may have been due to a lack of perceived benefits.

This study utilised facilities at a "healthy living centre." These centres are funded through the new opportunities fund of the National Lottery with a UK budget of £300m (\$460m, €470m)²⁹ and aim to promote health by helping people of all ages to maximise their health and wellbeing. Their health benefits have not previously been evaluated, and our study is the first published trial that shows they are effective.

A systematic review of Medline and a paper search of cited articles identified nine previous trials of exercise therapy in people with fibromyalgia. Each trial had 35–149 participants, making a total of 727. All reported positive findings with benefits lasting six months or longer in some trials.¹⁸ Two trials had negative results,^{13 14} and three had inadequate control groups.^{30–32} Three studies with global self rating outcome measures reported improvements in 51 (68%) participants (28–85% between studies).^{16 22 30} Our study design addressed the weakness of previous trials by being adequately powered, involving an appropriate control group, and including one year follow up.

Fibromyalgia is a common presentation in rheumatology clinics. The 136 patients we studied were selected from 7806 (2021 new) rheumatology clinic

What is already known on this topic

Fibromyalgia is common debilitating medically unexplained condition affecting around 1% of the population

Current treatments are unsatisfactory and most people remain the same after several years of treatment

Exercise as a treatment given by healthcare professionals in highly specialised centres is of some short term benefit

What this study adds

For people with fibromyalgia prescribed graded aerobic exercise is an effective treatment that leads to improvements in self reported health status

Prescribed exercise can be undertaken effectively in the community by personal trainers previously inexperienced in management of people with ill health

attendances in 1997. Their low SF-36 scores indicate high levels of disability, most were unemployed and receiving benefits, and many came from ethnic minorities. Our results indicate that such severely affected individuals benefit from a simple community based exercise intervention programme readily available through prescription.

Exercise treatment has limitations. Compliance is a considerable problem, giving high dropout rates. Reasons include the initial increases in pain and stiffness immediately after exercise and patients believing that exercise worsens the condition. Future strategies to increase the efficacy of exercise as an intervention should confront the issue of compliance. Potential strategies include additional cognitive behavioural therapy and providing physiological explanations for symptoms.^{33 34}

Contributors: SCMR designed and performed the study; DLS advised and supervised. Advice on planning the study was received from the department of psychological medicine at King's College Hospital, especially Dr Alicia Deale. Interventions were performed by personal trainers employed by Holmes Place plc. Statistical advice was given by Dr Peter Thomas, Dorset Research and Development Support Unit, and Drs Richard Hooper and Nora Donaldson, King's College Hospital, London. SCMR and DLS are guarantors.

Funding: This study was funded by a research training fellowship of the London region of the NHS executive.
