ABSTRACT

Objective To evaluate the effects of a community based integrated intervention for early prevention and management of chronic obstructive pulmonary disease (COPD) in China.

Design Cluster randomised controlled trial.

Setting Eight healthcare units in two communities.

Participants Of 1062 people aged 40-89, 872 (101 with COPD and 771 without COPD) who fulfilled the inclusion and exclusion criteria were allocated to the intervention or the usual care programmes.

Intervention Participants randomly assigned to integrated intervention (systematic health education, intensive and individualised intervention, treatment, and rehabilitation) or usual care.

Main outcome measures Annual rate of decline in forced expiratory rate in one second (FEV₁) before use of bronchodilator.

Results Annual rate of decline in FEV₁ was significantly lower in the intervention community than the control community, with an adjusted difference of 19 ml/year (95% confidence interval 3 to 36) and 0.9% (0.1% to 1.8%) of predicted values (all P<0.05), as well as a lower annual rate of decline in FEV₁/FVC (forced vital capacity) ratio (adjusted difference 0.6% (0.1% to 1.2%) P=0.029). There were also higher rates of smoking cessation (21% v 8%, P<0.004) and lower cumulative death rates from all causes (1% v 3%, P<0.009) in the intervention community than in the control community during the four year follow-up. Improvements in knowledge of COPD and smoking hazards, outdoor air quality, environmental tobacco smoke, and working conditions were also achieved (all P<0.05). The difference in cumulative incidence rate of COPD (both around 4%) and cumulative death rate from COPD (2% v 11%) did not reach significance between the two communities.

Conclusions A community based integrated intervention can have a significant impact on the prevention and

management of COPD, mainly reflected in the annual rate of decline in FEV₁.

Trial registration Chinese Clinical Trials Registration (ChiCTR-TRC-00000532).

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) has become a major public health problem worldwide because of its high and increasing prevalence, morbidity, and mortality.^{1,2} A recent report estimated that the global prevalence of COPD (stage II or over) is about 10% (12% in men and 9% in women).³ In China, COPD affects 8% of the population aged 40 or above⁴ and is one of the top diseases in the World Health Organization's ranking of burden of diseases.⁵ It is therefore necessary to develop a reliable intervention strategy for prevention and management of COPD to reduce the burden of this disease.

Current interventions for COPD (such as smoking cessation, rehabilitation, nutrition support, drug treatments, and psychosocial aids) are mainly carried out in hospitals on a case by case basis among patients who have already developed moderately or severely symptomatic COPD, while little attention has been paid to community based integrated interventions for earlier stages of the disease or before it has developed. Though there has been some progress with case based or hospital based interventions (such as improvements in exercise capacity, forced expiratory volume in one second (FEV₁), and health related quality of life, fewer admissions to hospital and acute exacerbations, and lower all cause mortality),⁶⁻¹⁰ the efficacy of such efforts are limited in the prevention of COPD among the general population in China. Few patients are diagnosed until they develop severe symptoms and signs, and pulmonary function tests are not routinely performed.⁴

We carried out a four year community based integrated intervention study to establish a reliable strategy for prevention and management of COPD at its early stages or before its development.

METHODS

Sampling and randomisation strategy

This community based cluster randomised controlled trial ran from September 2002 to May 2007 in Guangzhou city, China. A multistage randomised sampling strategy was used. Based on our previous epidemiological study,⁴ we used computer generated random selection to select one district (Liwang) from 12 districts in Guangzhou city and two communities (Xichun and Nanyuan) from nine comparable communities in the selected district (Liwang). Each was assigned to intervention or control by simple randomisation (a coin toss). We then used a computer generated random list to randomly select five of 15 healthcare units in Xichun and five of 17 healthcare units in Nanyuan for baseline survey. Two of the 10 healthcare units were excluded because they did not complete the baseline survey or refused the follow-up steps. A healthcare unit is a typical office unit in the community. From all the people in the units aged 40 and over, we selected about half (n=1062) using a systematic sampling method according to the house number. All sampled subjects were invited to participate in the study by a phone call or home visits. We allocated 872 people who fulfilled the inclusion criteria to integrated intervention or usual care in local communities. They underwent follow-up interviews with questionnaires and spirometry tests in the same hospital at baseline and follow-up survey. We also evaluated improvements in awareness of health knowledge related to COPD in random samples drawn from the two communities by using the same systematic sampling method (house number).

Participants

All included participants aged 40-89 in these two communities underwent a baseline screening survey to evaluate their potential to complete all the acceptable spirometry tests. They then completed questionnaires and gave written informed consent. Exclusion criteria included diagnosis with active tuberculosis, asthma or obvious bronchiectasis, cystic fibrosis, interstitial lung disease, or pulmonary thromboembolic disease; malignant tumour; history of thoracotomy with pulmonary resection; and uncontrolled or serious diseases and others that could potentially affect the spirometry test. Participants were lost to follow-up if we could not contact them or they had moved to another place, withdrew consent, refused to proceed, had invalid data, and were unable to complete the study.

Integrated intervention

Three groups in the intervention community ("healthy" population, high risk group, and patients with COPD classified by a baseline investigation) received the integrated intervention, including systematic health education and intensive and individualised intervention, treatment, and rehabilitation. To improve outdoor air quality in the intervention community, residents and the research team made intensive appeals to the local administration for relocation and technological upgrading of a neighbourhood cement factory. Because of these joint efforts, the cement factory received technological upgrading targeted to reduce air pollution and, in 2005, during the second year and third year of the intervention, relocated to suburban area more than 70 km away.

All participants underwent regular systematic health education—with health manuals, bulletins, broadcast television, video, networks, lectures, free consultation, and holding of relevant knowledge competitions—aimed at improving knowledge about COPD, eliminating unhealthy habits and behaviours, and improving indoor and outdoor air quality.

To maximise the effects of the intervention, individuals with COPD and those at high risk received additional and intensive interventions quarterly in the first year and annually in the next three years. These consisted of advice and instructions for smoking cessation, recommendations for better stoves, kitchen ventilation, work environment and living environment, and encouragement on adequate exercises. For smoking cessation we made smokers aware of the adverse effects of smoking on health and the benefits of not smoking, then assessed each smoker's willing to stop smoking and persuaded them to quit. Finally, we made personalised plans for each smoker who was willing to quit smoking. Regular telephone or home visits were performed every three months in the first year and annually thereafter to check smoking status and exposure to other risk factors, as well as to encourage compliance. To prevent relapses, we held advisory and recreational activities, lectures, and provided psychosocial support to help and teach smokers how to cope with withdrawal symptoms such as stress and increases

‡Data before intervention were missing for two people.

in body weight during smoking cessation. Nicotine replacement therapy (such as smoking cessation tea and patches) was recommended to relieve cravings for tobacco and withdrawal symptoms.

In addition, eligible patients with COPD were regularly prescribed a compound bronchodilator (Combivent; salbutamol 120 µg/puff and ipratropium 20 µg/puff) for a year and received quarterly visits. Pulmonary rehabilitation (such as physical exercise, pursed lip breathing, and abdominal breathing),⁹ low carbohydrate and high protein diets, and other non-pharmacological treatments were also recommended, and patients were helped to make plans in terms of training methods, duration of exercise, and intensity according to guideline. The box summarises the content of the integrated intervention.

Usual care

Participants in control communities were treated by healthcare providers or general practitioners in the usual manner. In case of deterioration, participants were treated with drugs by following the guidelines from the global initiative for chronic obstructive lung disease (GOLD) or referral to a respiratory specialist. The content and number of usual care services were not standardised.

Components and timings of integrated intervention

All participants (healthy population, those at high risk of COPD, patients with COPD)

Systematic health education

Items or components:

- Smoking hazards and instruction for smoking cessation
- Knowledge of COPD and relative risk factors

Scheme or timings:

- Health manuals, bulletins, etc, in public places quarterly
- A lecture and a large scale free consultation twice a year
- A competition of knowledge and free spirometry annually

Participants at high risk of COPD, patients with COPD

Intensive and individualised interventions

Items or components:

- Advice and instruction for smoking cessation
- Advice to improve air pollution and work environment
- Encouragement to exercise and improvement in living environment

Scheme or timing:

- A lecture, a club activity, and a visit quarterly in the first year and annually thereafter

Patients with COPD only

Treatment and rehabilitation

Items or components:

- Treatment with compound bronchodilator for a year
- Advice and guidance for individualised rehabilitation, drug use, and diet
- Questionnaire and spirometry quarterly in the first year and annually thereafter

Scheme or timing

- A visit each quarter in the first year for treatment with compound bronchodilator, advice, and guidance

Baseline and follow-up survey and outcomes measurement

All participants filled in questionnaires and underwent spirometry at the baseline and at annual follow-up survey. Considerable efforts were made to ensure high quality data (see appendix 1 on bmj.com). Our primary outcome was the annual rate of decline in FEV₁ before use of a bronchodilator in the two communities. The secondary outcomes included changes in cumulative incidence rate, cumulative case death rate for COPD, change in awareness of knowledge related to COPD, and change of risk factors for COPD (such as active and passive smoking, outdoor air pollution, living and working environment) from baseline in the two communities.

Questionnaires

The questionnaires used at baseline and follow-up visits had previously been used in the Burden of Obstructive Lung Disease study in Guangzhou³ and COPD epidemiological survey in China⁴¹¹ (see appendix 2 on bmj.com). Additional questionnaires (COPD management and St George's respiratory questionnaire, SGRQ) were used for patients with COPD. We assessed and classified changes in risk factors (such as active and passive smoking, outdoor air pollution, living and working environment) from baseline as improved, no change, or worse, based on participants' self report. From 2002 to 2007 the local bureau of environmental protection and environmental monitoring centre continuously measured concentrations of sulphur dioxide (SO₂), nitrogen dioxide (NO₂), dust deposition, and sulphation rate with an auto-monitoring system.

We classified participants' smoking status at each visit as never smoked, smoking cessation (namely, former smoking), and current smoker. Participants who had smoked for at least six months or had smoked at least 100 cigarettes in their lifetime were defined as an ever smoker,^{12 13} otherwise they were classed as never smoking. Current smokers were those who were smoking tobacco products at the time of the survey and included continual and intermittent smokers and those who had quit but restarted or relapsed or had quit but for less than six months. Smoking cessation (former smoking) was defined as having not smoked tobacco products for at least six months at the time of survey. We give the rate of smoking cessation during the study period as the ratio of numbers who gave up smoking during the study period to the numbers of current smokers at baseline. Environmental tobacco smoke was assessed by asking participants whether they could smell tobacco smoke at home or at work for at least an hour a day at each visit.¹³ We classified this by improvement (including no exposure and decreased exposure from baseline) or no improvement (the same and increased exposure from baseline) based on self reports. Exposure to occupational dusts/gases/fumes for more than a year over a participant's lifetime was deemed as having occupational exposure.

Spirometry

Trained technicians performed spirometry in accordance with the criteria recommended by the American

Fig 1 | Flow of participants through trial. Missing indicates participants with missing data because of failure of contact, being out, or inability to finish spirometry test; they might attend next follow-up visits. Withdrew indicates cumulative number of participants who withdrew consent (refusal); they were invited to complete investigation with questionnaire before dropping out

Thoracic Society¹⁴ and the Europe Respiratory Society.¹⁵ At least three acceptable and two reproducible measurements (that is, largest and next largest values of forced vital capacity (FVC) and FEV₁ within 150 ml or 5%) that met with the criteria^{14,15} were required for each individual. The largest value of FVC and FEV₁ was reported (see appendix 1 on bmj.com). To minimise the variation of the results, on each of the four testing days during the four year study (one day a year) spirometry was performed for each participant at about the same time of day. The use of short and long acting bronchodilators was prohibited within 12 or 24 hours before the test, respectively. A portable spirometer (Micro Medical, Chatham, Kent) was used and the test was done after inhalation of 400 µg of salbutamol for 15-20 minutes (Ventolin,

GlaxoSmithKline) via a 500 ml spacer for those participants whose FEV₁/FVC ratio before bronchodilation was <70%. Definition of COPD and its severity stages were according to the global initiative for chronic obstructive lung disease.¹⁶ We used reference values from the European Coal and Steel Community 1993 for predicted values of FEV₁, adjusted with conversion factors for the Chinese population (male 0.95 and female 0.93).¹⁷

Statistical analysis

To detect the difference of 20 (SD 80) ml in FEV₁ between two groups with 80% power, a two sided type I error of 5%, a design effect of 2.2, and an intra-cluster correlation coefficient (ICC or ρ , defined as the ratio of the variance between groups to the total variance) of 0.012 based on a pilot study, we calculated that we needed eight clusters of 130 participants according to usual formula,¹⁸ allowing 20% loss during follow-up. The statistical analysis was performed with the SAS version 9.1 software (SAS Institute, Cary, NC).

We included in the analyses all recruited participants who had received the allocated intervention or usual care, except those without any acceptable observation data after randomisation. Baseline characteristics were evaluated with a *t* test or analysis of variance for continuous variables and a χ^2 test for dichotomous variables. Improvements in awareness and risk factors for COPD between the two communities were analysed with hierarchical logistic models, taking account of the clustering nature of the data. The latest valid values with respect to change of awareness and risk factors for COPD were regarded as the endpoint values for those who did not complete follow-up.

Preliminary data analysis showed that the pattern of change in absolute values of FEV₁ (ml), percentage of predicted value, and FEV₁/FVC ratio (%) from baseline was about linear and varied according to baseline data. To access longitudinal changes of FEV₁ (often called FEV₁ "slope") between the intervention and control community, we applied SAS's Proc Mixed procedure, which admits missed values, to build multi-level mixed models by adjusting for confounding and clustering effects. Potential confounders were taken into account, and we included baseline FEV₁ (or FEV₁/FVC ratio), age, sex, education, smoking status, environmental tobacco smoke, COPD, body mass index (BMI), and occupational exposure to dusty/gases/fumes in the final model. The selection of the appropriate type of covariance structure was accomplished by considering the biological features of the outcome variable and also by choosing the smallest Akaike's information criterion (AIC) after fitting models with alternative covariance structures. The final models included an auto regressive order 1 structure covariance (AR(1)) to count for serial correlation of FEV₁ and FEV₁/FVC within individuals and an unstructured covariance to account for random variation in the intercept and slope parameters between

†Post-bronchodilator data used in participants with COPD; bronchodilation not carried out those without COPD. ‡Reversibility of COPD defined as improvement in FEV₁ from pre-bronchodilator ≥12% and ≥200 ml post-bronchodilator.

§Two communities had similar characteristics at baseline except for occupational history of dust/gases/fumes (P<0.001).

¶Data missing for 12 participants (seven in intervention community and five in control community).

individuals and healthcare units. Such an analysis was repeated in subgroups.

We used a mixed model to compare the change in air pollutants (log transformed) in the two communities. As preliminary analysis showed significant or close to significant correlations between pairs of pollutants (data not shown), they can be regarded as a correlated “package” of pollutants with a similar pattern relative to each other across the four year study period. We extracted a variable to represent these air pollutants using factor analysis for SO₂, NO₂, dust deposition,

and sulphation rate. The correlation of adjusted FEV₁ at each year with average level of air pollutants from baseline was analysed with partial correlations analysis. Significance was set at P<0.05.

RESULTS

Baseline characteristics and follow-up rate

Of 1062 sampled participants, 872 (82%) who fulfilled the criteria of study were allocated intervention or usual care. Of these, 845 (80%) completed follow-up at the first year, 824 (78%) at the second year, 815 (77%) at the third year, and 819 (77%) at the fourth year. A total of 872 (82%) completed the baseline survey and at least one follow-up investigation with questionnaires (83% in the intervention community and 81% in the control community), and 860 (80%) had acceptable data for spirometry test from at least two follow-up visits (including baseline) (82% in the intervention community and 80% in the control community) (fig 1). There were 840, 822, and 793 participants who completed an acceptable spirometry test for three, four, and five years (including baseline), respectively.

There was no difference in causes of allocation failure between the two communities (P=0.11, fig 1) and no difference in the main basic demographic characteristics (see table A in appendix 3 on bmj.com). There was a significant difference in causes of uncompleted follow-up (dropping out) for spirometry tests between the communities at the end of study (P=0.03, fig 1). The two communities were drawn from a single district and were similar in socioeconomic status (that is, annual averaged income and education level), availability of and access to health services, current smoking prevalence, awareness of COPD, and main demography at baseline (table 1). At baseline the intervention community had a higher concentration of SO₂ and sulphation rate in outdoor air than the control community (P<0.001 and P=0.018, respectively), but there was no difference at the end of study (fig 2). Compared with the control community, the intervention community had a greater rate of decline in SO₂ concentration (0.051 µg/m³ per year (95% confidence interval 0.019 to 0.083) P=0.003) and dust deposition (0.051 (0.019 to 0.083) kg/km²/month per year, P=0.003) during follow-up, and there was a difference of borderline significance between the two communities in the slope of concentration of NO₂ (0.033 (−0.013 to 0.079) µg/m³ per year, P=0.092) and sulphation rate (0.020 (−0.001 to 0.041) µg SO₃/100 cm² PbO₂/day/year, P=0.059).

Most baseline demographic characteristics of participants who completed questionnaires during follow-up were comparable between the two communities, except for occupational dusts/gases/fumes exposure (P<0.001) (table 2). Similar results were observed among those 860 people who had completed acceptable spirometry tests (data not shown).

FEV₁ and FEV₁/FVC ratio

During follow-up, the mean rate of decline in FEV₁ was about 19 ml and 0.9% of the predicted value per

Table 3 | Difference between two communities in annual rate of decline in FEV₁ (ml/year, predicted %/year) and FEV₁/FVC ratio (%/year) in participants aged ≥40

	Intervention community		Control community		Adjusted difference*	
	No	Mean (SE)	No	Mean (SE)	Mean (95% CI)	P value
Total population						
FEV ₁ (ml/year)	429	30 (3)	431	49 (3)	19 (3 to 36)	0.023
FEV ₁ (predicted %/year)	429	0.3 (0.2)	431	1.2 (0.2)	0.9 (0.1 to 1.8)	0.033
FEV ₁ /FVC (%/year)	429	-0.5 (0.1)	431	0.4 (0.1)	0.6 (0.1 to 1.2)	0.029
Participants without COPD						
FEV ₁ (ml/year)	382	26 (3)	379	50 (3)	20 (3 to 37)	0.025
FEV ₁ (predicted %/year)	382	0.1 (0.2)	379	1.2 (0.2)	1.1 (0.2 to 2.0)	0.021
FEV ₁ /FVC (%/year)	382	-0.5 (0.1)	379	0.4 (0.1)	0.7 (0.1 to 1.2)	0.019

*Adjusted for baseline FEV₁ (or FEV₁/FVC), age, sex, education, smoking status, COPD, BMI (body mass index), and occupational exposure to dusty/gases/fumes) and clustering effects.

year higher in the control community than in the intervention community (49 ml/year *v* 30 ml/year; 1.2% *v* 0.3% of predicted values per year). The FEV₁/FVC ratio declined in the control community but not in the intervention community (0.4% *v* -0.5% a year). After adjustment for confounders and clustering effects, statistical effects persisted for intervention community in the rate of decline ($P < 0.05$, table 3 and fig 3). At the end of the study the intervention community had a significantly greater estimated mean FEV₁ and FEV₁/FVC ratio than the control community ($P < 0.05$, fig 3). In the total population, the differences were 71 ml (95% confidence interval 47 to 94) for FEV₁, 3.0% (1.7% to 4.2%) for predicted value, and 3.1% (2.4% to 3.9%) for FEV₁/FVC ratio. Similar results were observed among participants without COPD, with figures of 85 ml (61 to 110, 4.3% (3.0% to 5.6%), and 3.0% (2.3% to 3.8%), respectively (fig 3).

Further subgroup analyses showed similar results in the rate of decline of FEV₁ and the change of FEV₁/FVC ratio with regard to the effects of intervention among people without COPD (table 3 and fig 3). Results were also similar in participants at high risk (see table B in appendix 3 on bmj.com). There was no significant difference between patients with COPD from the two communities in the rate of decline of FEV₁ within four years or in FEV₁/FVC ratio (table B in appendix 3 on bmj.com).

As shown in the subgroup analysis of smoking, in intervention communities the decline in FEV₁ values (both absolute value (ml) and percentage of predicted value (% predicted)) was slower in those who had never smoked or had quit smoking than in current smokers after adjustment for confounders and clustering effects ($P < 0.05$, table C in appendix 3 on bmj.com). A similar pattern but with no difference in decline of FEV₁ was founded among subgroups by smoking status in the control community (table C in appendix 3 on bmj.com).

Further analysis of non-smokers (including never smokers and former smokers) showed that non-smokers with reported improvement in exposure to environmental tobacco smoke seemed to have a slower rate of decline of FEV₁ by 0.6% of predicted value per year

than those without any improvement, after adjustment for confounders and clustering effects (table D in appendix 3 on bmj.com). Non-smokers in the intervention community still had a slower rate of decline of FEV₁ than those in the control community by 23 ml (12 to 33) per year and 1.2% (0.7% to 1.8%) of predicted value per year (table D in appendix 3 on bmj.com). Differences between the two communities in current smokers were smaller (data not shown).

Changes in awareness of and risk factors for COPD

By the end of the study, awareness of COPD in the intervention community improved from 20% to 77% compared with 18% to 22% in the control community ($P < 0.001$). Similarly, more people reported awareness of the risks or hazards of cigarette smoking, despite no significant difference for awareness of COPD and related risk factors at baseline (table 1 and table 4).

Compared with the control community, more people in the intervention community reported an improvement in outdoor air pollution (27% *v* 19%), working conditions (6% *v* 3%), and environmental tobacco smoke (61% *v* 52%) (table 4). The rate of smoking cessation in intervention community was 21%, which is higher than that in the control community (8%) (table 4). Although there were no significant differences between the two communities in cumulative incidence of COPD (both around 4%) and cumulative death rate of COPD (2% *v* 11%), there were differences in cumulative death rate from all causes in the total population during follow-up (1% *v* 3%, $P = 0.009$) (table 4). We found no overall difference with regard to quality of life (scores of St George's respiratory questionnaire) among patients with COPD between two communities. Patients with COPD who had received integrated intervention for a year, however, showed improved quality of life as indicated in symptom scores on the respiratory questionnaire and experienced less exacerbation of COPD compared with those in the control community (data not shown).

Changes of outdoor air quality

As shown in figure 2, there was a greater decline in SO₂ concentration (0.051 (0.019 to 0.083) µg/m³ per year, $P < 0.003$) and dust deposition (0.051 (0.019 to 0.083) kg/km²/month per year, $P < 0.003$) in the intervention community than in the control community. There were borderline differences between the two communities in the slope of concentration of NO₂ (0.033 (-0.013 to 0.079) µg/m³ per year, $P > 0.09$) and sulphation rate (0.020 (-0.001 to 0.041) µg SO₃/100 cm² PbO₂/day/year, $P > 0.05$). These results indicate that outdoor air quality was significantly improved in intervention community compared with the control community.

DISCUSSION

Principal findings and comparison

Community based integrated intervention at earlier stages of COPD and before its development could significantly slow the decline in FEV₁. To our knowledge,

Fig 2 | Annual log mean levels of air pollutants in intervention and control communities, 2002–2007, with 95% confidence intervals

few studies have directly elucidated the effects of integrated intervention on COPD at the community level. The multiple risk factor intervention trial (MRFIT),¹⁹ which focused on coronary heart disease, found no overall differences in the rate of decline in FEV₁ between two communities (usual care and special intervention that included an intensive smoking cessation programme), but FEV₁ declined slowly among smokers who did not take β blockers in the tobacco cessation intervention group compared with controls. In Lung Health Study,²⁰ aggressive smoking interventions were given to smokers with mild COPD, and this resulted in a slower decline in FEV₁ in the first year between the two groups, but there were no differences in the next three years. In contrast, our community based interventions targeted more aspects of COPD management and prevention at its earlier stages or before development. As a result, we saw a slower rate of decline in FEV₁ among participants in the intervention community than in the control community. Meanwhile, there was an improvement in FEV₁/FVC ratio among participants in intervention community, especially among those at high risk of COPD.

The benefits of our integrated intervention could have resulted from a combination of smoking cessation, efforts to improve environmental air quality, self management training for prevention of COPD, and other positive factors.

Smoking

Smoking accelerates the decline in FEV₁, but it can be reversed by quitting smoking.^{6 19–23} In our study there was a greater cessation rate in the intervention community than in the control community (21% *v* 8%). Cessation was associated with a reduced rate of decline in

FEV₁ (by –27 ml/year) in the intervention community (table C in appendix 3 on bmj.com). In the control community, there was no significant difference in annual rate of decline in FEV₁ between those who did and did not stop smoking, which could be explained by the low numbers of participants who had quit smoking and the fact that some of them gave up smoking because of worsening health status. Therefore, there seems little question that smoking cessation greatly contributed to the outcome of the intervention.

Other factors besides smoking cessation should also strengthen the positive benefits of intervention. We found a significant difference in the rate of decline in FEV₁ between the two communities after adjustment for smoking cessation, as well as in non-smokers (table D in appendix 3 on bmj.com). As shown in our results, more people reported having improved exposure to environmental tobacco smoke from baseline in the intervention community than in control community during follow-up. Those who reported having reduced exposure to environmental tobacco smoke at the end of study had a slower rate of decline in FEV₁ than those without reduced exposure (table D in appendix 3 on bmj.com). These observations indicated that changes in exposure to environmental tobacco smoke might have contributed to the effects of intervention.

Air pollution

As an important part of the community based intervention programme and after joint efforts of members of the study team, public, and government, a neighbourhood cement factory near the intervention community was eventually relocated and upgraded in 2005 with the main purpose of decreasing air pollution. This resulting improvement in outdoor air pollution was

Fig 3 | Estimated mean FEV₁ (ml and % predicted) and FEV₁/FVC ratio (%) over time in both communities among total population and those without COPD. * $P<0.05$ for estimated mean after adjustment for clustering and confounding factors (baseline FEV₁ (or FEV₁/FVC ratio), age, sex, education, smoking status, environmental tobacco smoke, COPD, BMI, and occupational exposure to dust/gases/fumes). P values in figure refer to comparison between communities in rate of decline in FEV₁ and FEV₁/FVC ratio after adjustment for above confounders and clustering effects

noted in laboratory reports from a perennial monitoring site in the intervention community designated by the local bureau of environmental protection (fig 2). In contrast, data from the monitoring site in the control community showed no improvement in air quality. After adjustment for potential confounders and cluster effects, there were still significant differences in the surrogates for the change in outdoor air quality between the two communities, and similar results were observed among those who had never smoked (table D in appendix 3 on bmj.com). In addition, there was significant correlation between adjusted FEV₁ and FEV₁/FVC ratio and averaged air pollutants over time (table E in appendix 3 on bmj.com). Therefore, improvement in air pollution within the intervention community should also have contributed to the slower decline in FEV₁, which is consistent with previous published literature.²⁴

Education and knowledge

Though health education did not seem to have obvious and directly positive effects on the rate of decline in FEV₁ (data not shown), previous trials have shown that it can help to reduce exacerbation of and mortality from COPD and improve quality of life.^{9,25,26} As lower respiratory disorders or acute exacerbations of COPD also promote decline in FEV₁ in current smokers with mild COPD,²⁷ reduction in acute exacerbations should also have a positive effect on decline of FEV₁. Furthermore, as COPD is considered a disease in which limitation of air flow associated with harmful gases and fumes is not fully reversible, education targeted at avoidance of risk factors might have played an important role in reducing the decline of FEV₁. At baseline 78% of the participants knew little about COPD and over 65% had never received health education. This poor level of COPD prevention among people at baseline could

*Adjusted for clustering effects. Odds ratio >1 means that over four years more people in intervention community than control community reported improvement in variables. After adjustment for clustering effect, when variables were considered as ordered categories and cumulative logit model was used, odd ratios were 1.66 (1.24 to 2.22, $P<0.001$) for awareness of hazards of smoking, 1.52 (1.17 to 1.97, $P<0.002$) for outdoor air pollution, and 1.94 (1.09 to 3.44, $P=0.024$) for working conditions.

†After intervention 341 in intervention community and 331 in control community randomly sampled from entire population completed short questionnaire of knowledge on health.

‡Data missing for four in intervention community and one in control community.

§Data missing for seven in intervention community and five in control community.

¶Four former smokers at baseline (two in each community) had started smoking at end of study.

**Diagnosis of COPD was according to global obstructive lung disease in 12 participants. Excludes participants who did not undergo post-bronchodilator test and those with pre-bronchodilator $FEV_1/FVC \geq 70\%$.

also explain the greater outcomes achieved by this well designed health education programme in our integrated intervention.

Strengths and limitation of the study

Our integrated community based intervention achieved positive effects, especially for people at high risk of COPD. As COPD is a disease that can be caused by multiple factors, an integrated intervention, which was formed and refined from published methods (such as smoking cessation, reduce of air pollution,

rehabilitation, nutrition support, drug treatment, and health education),^{6-9 19 20} should be more effective regarding development and progression of the disease than a single intervention targeted at a sole factor. COPD has a long term course with chronic progression and is often underdiagnosed, and thus a community based integrated intervention at earlier stages or before development of COPD would have more impact than a hospital intervention among patients who have already developed moderately or severely symptomatic COPD. Our hypothesis is consistent with the results of several recent studies.²⁸⁻³⁰ These studies have shown that FEV_1 declined more rapidly in patients with milder COPD, indicating that more attention should be paid to patients with earlier stage disease. Our results further emphasise the importance of intervention before the development of COPD.

Our study had certain limitations. Firstly, fewer participants in the intervention community had occupational exposure to dust/gases/fumes at baseline. We consider that this imbalance did not compromise our conclusion because we found a significantly slower rate of decline in FEV_1 in the intervention community even after adjustment for these factors. This was also the case in further analyses stratified by occupational exposure to dust/gases/fumes (fig A in appendix 4 on [bmj.com](http://www.bmj.com/)). Secondly, changes in risk factors such as smoking status were not based on laboratory measurement but on self report. This did not change our conclusions as we also obtained information from close family members of the participants. Our results also showed that smoking cessation slowed the rate of decline in FEV_1 (table B in appendix 3 on [bmj.com](http://www.bmj.com/)), confirming results of other studies.^{6 19-21} In addition, despite there being a correlation between adjusted FEV_1 and air pollutants over time (table E in appendix 3 on [bmj.com](http://www.bmj.com/)), we could not further confirm the correlation of annual rate of decline in FEV_1 and change of outdoor air quality because we recruited only two communities. Finally, we evaluated the annual decline of FEV_1 only before use of a bronchodilator, not after, because a bronchodilator test was not performed among patients without COPD at baseline. COPD was defined by a FEV_1/FVC ratio of below 0.7 after use of bronchodilator. This criterion, however, could result in overdiagnosis in older people and underdiagnosis in younger people.³¹ Diagnosis by percentage of FEV_1/FVC ratio below the fifth centile should be more precise.³² Unfortunately, the lower limit of normal for FEV_1/FVC ratio for people in China is not currently available. In addition, a fixed ratio of FEV_1/FVC below 0.7 is still recommended by the global initiative for chronic obstructive lung disease (GOLD) and is used by many other investigators.³³ We therefore used the fixed ratio of 0.7 for diagnosis of COPD in our study.

Conclusion and implications

In conclusion, this community based integrated intervention helped to prevent and control COPD through improved awareness of COPD, reduced risk factors for COPD, and a reduction of the rate of decline in FEV_1 .

WHAT IS ALREADY KNOWN ON THIS TOPIC

COPD is a chronic progressive disease caused by multiple factors such as smoking and air pollution; a single factor intervention will therefore have limited effects

Little attention has been paid to interventions at an earlier stage at community based level

WHAT THIS STUDY ADDS

Community based integrated interventions can decrease the rate of decline in FEV₁, probably from the combined effects of smoking cessation and improvements in air pollution

Though the methods used in this integrated intervention and our experience with it might be culture and condition specific, the outcomes that smoking cessation, improvement in air pollutants, and reduction in environmental tobacco smoke have contributed to the slowing rate of decline in FEV₁ should apply throughout the world.

We thank Xiaoyi Yang (National Cancer Institute, NIH, USA) and Guangqiao Zeng (State Key Laboratory of Respiratory Disease, Guangzhou Institute of Respiratory Diseases, Guangzhou Medical University, China) for their help with English, and Mei Jiang (State Key Laboratory of Respiratory Disease, Guangzhou Institute of Respiratory Diseases, Guangzhou Medical University, China) for her help with the statistical analysis. We also thank Jinquan Liang, Tianming Dong, and Yexin Liu (Bureau of Environmental Protection of Liwan District, Guangzhou Environmental Monitoring Center, Bureau of Environmental Protection of Guangzhou Municipality) for their help in measuring air pollution.

Contributors: YZ collected the data and monitored data collection, planned the statistical analysis, analysed the data, and drafted and revised the manuscript. GH and DW implemented the trial and conducted the intervention. SW, YW, and ZL conducted and monitored data collection. JH and ZS conducted intervention. GP and SL conducted data collection. JL planned the statistical analysis and drafted and revised the paper. JZ monitored data collection and drafted and revised the paper. JW drafted and revised the paper. PR and NZ initiated and designed the project, monitored data, and drafted and revised the paper. PR, NZ, and YZ are guarantors.

Funding: This study was funded by a grant from the Chinese Central Government key research projects of the 10th National Five-year Development Plan 2001BA703B03(A) and in part by Guangdong Key Research Project grant B30301. The researchers were independent from funders. The study funders had no influence on the study design, collection, analysis, interpretation of data, writing of the report, and the decision to submit the article for publication.

Competing interests: All authors have completed the Unified Competing Interest form at www.icmje.org/coi_disclosure.pdf (available on request from the corresponding author) and declare: no support from any institution for the submitted work; no financial relationships with any institutions that might have an interest in the submitted work in the previous 3 years; no other relationships or activities that could appear to have influenced the submitted work.

Ethical approval: The study protocol was approved by medical ethic committee of Guangzhou Institute of Respiratory Diseases and written informed consent was given by all participants.
