FIG. 2.—Radiographs taken five weeks later, showing good callus formation.
regarding the arterial supply as well as the venous phase. If a hepatoma with secondary portal-vein thrombosis is suspected then it is the procedure of choice, for hepatoma and secondary neoplasm in the liver are supplied exclusively by the hepatic artery (Breedis and Young, 1954). The question will arise of which of the arteries should be catheterized. This has to be decided individually. If the only information required is whether the portal vein is patent, then the superior mesenteric artery is the one to choose, since this is generally easier than coeliac-axis catheterization and consistently affords a high concentration of contrast in the portal vein.

On the other hand, coeliac arteriography shows the splenic as well as the portal vein and is the better procedure if an arterial lesion such as hepatoma or the very rare splenic arteriovenous aneurysm (Murray, Thal, and Greenspan, 1960) is suspected. We have not tried the technique described by Boijsen et al. (1963) in which both vessels are catheterized and contrast is injected simultaneously. This results in passage of contrast medium into all branches of the portal system and should provide maximal contrast in the portal vein, but the use of two catheters must undoubtedly lengthen the procedure and does not appear to be justified routinely.

Finally, it is necessary to emphasize that arteriography is a safe procedure, the only risk being that of a percutaneous femoral puncture. The wider availability of this procedure means that no patients with portal hypertension need now be operated on in whom the portal venous system has not been completely visualized pre-operatively.

**Summary**

A technique of arteriography described for use with standard x-ray equipment. In 36 (86%) of the 42 patients examined the artery was successfully catheterized and in 26 (72%) of them good visualization of the portal venous system was obtained. Superior mesenteric arteriography is of particular value in the pre-operative assessment of patients with portal hypertension in whom the spleen has been removed. Coeliac arteriography is technically more difficult and the indications for its use are considered.

We thank Professor Sheila Sherlock and Dr. W. B. Young for their encouragement and advice. We would also like to thank Mr. John Hendley and the radiographers, especially Miss B. Whittal, for technical assistance.

**Dissecting Microscope Appearances of the Gastric Mucosa**

S. N. SALEM,*† M.B., CH.B., M.R.C.P.ED.; S. C. TRUELOVE,* M.D., F.R.C.P.

[With Special Plate]

Since the introduction by Wood et al. (1949) of a simple and safe instrument for peroral gastric biopsy, this method or some modification of it has been widely used to study the pathology of the gastric mucosa. Although many histological studies of gastric biopsy specimens have been made, we have been unable to find any account of the changes visible in such biopsy specimens when they are examined under a dissecting microscope.

In the course of a study of the gastric and small-intestinal changes in ulcerative colitis (Salem et al., 1964a, 1964b) we took the opportunity to study some of the gastric biopsy specimens under the dissecting microscope and to compare the appearances with the results of subsequent histological examination.

**Results**

The gastric biopsy specimens were obtained by means of a Crosby-Kugler capsule, which was introduced for small-intestinal biopsy (Crosby and Kugler, 1957) but has also been found convenient for gastric biopsy (Floh and Sheehy, 1962; Salem et al., 1964a). The specimens from 48 patients have been examined under the dissecting microscope; in some patients separate specimens were obtained from the cardia, the body, and the pyloric end of the stomach under fluoroscopic control using an image intensifier and television monitor.

We found that the appearances of the fundic mucosa under the dissecting microscope varied from specimen to specimen and that three main categories could be recognized which corresponded to various histological appearances. The three categories are as follows:

*Category I* (corresponding to normal histological appearances).—Under the dissecting microscope there is a uniformly regular pattern of papillae, each one of which has a round hole in its centre, representing the mouth of a gastric gland. The papillae are packed close together. The colour varies from a pale pink to a faint red. The general appearance can be compared to that of a honeycomb, or Morocco leather (Special Plate, Fig. 1).

*Category II* (corresponding to superficial gastritis on histological examination).—The papillae are swollen, congested, and reduced in number. The gastric-gland openings are slit-like and look deep, owing to surrounding swelling (Special Plate, Fig. 2). Hyperaemia is often obvious. (Sometimes patches of mucosa with these characteristics are interspersed with normal areas, just as histologically the appearances of superficial gastritis may be patchy.)

Red-cell Aplasia with Carcinoma of the Bronchus

The literature contains 83 reports of pure red-cell aplasia (Andersen and Ladefoged, 1963; Schmid, Kiely, Pease, and Hargraves, 1963). An association with a thymic tumour has been demonstrated in 44 cases, but the condition has not been described with other tumours. The present report describes a patient in whom red-cell aplasia occurred together with a bronchial carcinoma. The serum of this patient contained a factor which inhibited erythropoiesis in rabbits but which was absent after irradiation of the tumour.

Case Report

A man aged 68 attended his doctor for a routine medical examination prior to his retirement from a job as a labourer in the engineering industry. He was found to be pale and was referred to Cardiff Royal Infirmary in February 1961 for investigation. His only complaint was that of tiredness. He had smoked at least 20 cigarettes each day for many years and had experienced a productive cough for three years.

Physical examination confirmed the mucosal pallor. His spleen was palpable on deep inspiration but there were no other abnormal physical signs.

Investigations.—Haemoglobin 6.7 g./100 ml. M.C.H.C. 32%, M.C.V. 140 cubic microns. Reticulocyte count 1%. W.B.C. 3,900/ c.mm., normal differential count. Platelets 265,000/c.mm. Blood film: normochromic macrocytic red cells, with anisocytosis and poikilocytosis. E.S.R. 50 mm. in 1 hour (Westergren). Direct Coombs test negative. Serum vitamin B12 141 mg./ml. Serum proteins: total 6.7 g./100 ml. (albumin 4.0 g.). Blood urea 33 mg./100 ml. Sternal marrow aspirate showed only scanty red-cell precursors, which were normoblastic in type. They comprised 4% of the total cells. The myeloid series and megakaryocytes were normal. Trephine marrow biopsy from the iliac crest showed slight hypopcellularity. Gastric analysis revealed a histamine-fast achlorhydria. Barium-enema examination showed diverticulosis of the colon. Chest radiograph was normal. Faecal occult blood was negative.

The patient made no response to injections of vitamin B12 and was believed to have a hypoplastic anaemia. He required blood transfusions to prevent a serious fall in haemoglobin, and during the next 21 months he received 60 pints (34 litres) of blood.

Three months after his first admission to hospital he developed a transient pyrexial illness with a polyarthritis involving the lumbar spine, ankles, knees, and hands. The pyrexia responded to penicillin. The cause of the illness was uncertain. His E.S.R. reached 150 mm. in 1 hour (Westergren) but his peripheral white-cell count remained within normal limits. Serum electrophoresis at this time showed a raised gamma-globulin. Shortly after this illness clubbing of the finger-nails was noted for the first time.

In August 1962 the patient's haemoglobin was 11.5 g./100 ml., M.C.H.C. 33%, with the aid of transfused blood. The reticulocyte count was 20,400/c.mm. and had been at about this level for the previous year. Serum iron was 203 μg./100 ml. and total iron-
