Experimental and clinical evidence both suggest that there is some connexion between the metabolism of vitamin B₁₂ and that of cyanide, and that smoking, which is associated with a high cyanide intake—for example, Darby and Wilson (1967)—may adversely affect B₁₂ metabolism (Boxer and Rickards, 1952; Wokes and Picard, 1955; Braekkan, Nja, and Utne, 1957; Wokes, 1958; Smith, 1961; Smith, Duckett, and Waters, 1963; Smith, 1964; Smith and Duckett, 1965; Matthews, Wilson, and Zilkha, 1965; Wilson and Matthews, 1966; Lindstrand, Wilson, and Matthews, 1966; Smith and Foulkes, 1966). The hypothesis that interconnected disturbances of cyanide/B₁₂ metabolism may be concerned in the pathogenesis of tobacco amylobryopathy, the retrobulbar neuritis of pernicious anemia, Leber’s optic atrophy, and certain tropical neurological syndromes apparently associated with a high cyanide intake from cassava (Smith, 1961; Wilson, 1965; Montgomery, 1965; Wilson and Langman, 1966; Monekosso and Wilson, 1966; Freeman, 1967; Chisholm, Bronte-Stewart, and Foulks, 1967) makes it essential to obtain further information about the inter-relationships between an increased exogenous cyanide load, cyanide/thiocyanate metabolism, and bodily handling of vitamin B₁₂.

So far the observations apparently providing a direct link between smoking and B₁₂ metabolism are few. They include: (1) the observation that there may be a slight or moderate increase in cyanocobalam in the plasma of some heavy smokers (Lindstrand, Wilson, and Matthews, 1966); (2) the finding that a larger proportion of serum B₁₂ is extractable in the absence of added cyanide in smokers than in non-smokers, which may be related to (1); and (3) the finding of a negative correlation between plasma cyanide concentration and that of total serum B₁₂ (Matthews et al., 1965; Wilson and Matthews, 1966). This last relationship could be connected with a tendency for chronic administration of cyanide to deplete body B₁₂ stores (Braekkan et al., 1957), and the present investigation was made to explore this possibility further.

Methods

Two groups of healthy subjects were studied—18 non-smokers (16 men and 2 women, mean age 27) and 19 smokers (16 men and 3 women, mean age 29). Eighteen of the smokers smoked cigarettes (mean consumption 20 per day) and one smoked a pipe (1 oz. (28 g.) per day). Twenty-four-hour urine collections were made in containers containing 1 g. of neomycin, and aliquots of urine deep-frozen until analysis. Urine thiocyanate was estimated spectrophotometrically (Wilson and Matthews, 1966). Blood was taken for serum B₁₂ estimation on the day of the urine collection. Serum and urine B₁₂ were estimated by radioisotopic assay (Matthews, Gunasegaram, and Linnell, 1967) after extraction with cyanide-containing buffer.

Results and Discussion

The results showed definite interrelationships between smoking, urine thiocyanate excretion, which is an index of the exogenous cyanide load, and serum and urine B₁₂ (Tables I and II; Fig. 1). The mean thiocyanate excretion in smokers was more than double that in non-smokers. The urine B₁₂ excretion was significantly increased in smokers (P=0.02). In smokers and non-smokers, taken together, there was a positive correlation between urine thiocyanate excretion and urine B₁₂ excretion. There was a negative correlation between thiocyanate excretion and serum B₁₂ concentration. In smokers alone, this latter correlation was more pronounced, and the tendency for high thiocyanate excretion to be associated with relatively low serum B₁₂ concentrations was striking (Fig. 2). Extrapolation of the regression line in Fig. 2 suggests that if the urine

![FIG. 1.-Urine thiocyanate excretion and urine B₁₂ excretion in smokers and non-smokers.](http://www.bmj.com/ Br Med J. first published as 10.1136/bmj.2.5599.215 on 27 April 1968. Downloaded from http://www.bmj.com on 27 October 2023 by guest. Protected by copyright.)
thiocyanate excretion reached 300–400 μmoles/24 hours, sub-
normal serum B₁₂ concentrations would be expected.

Summarized, the results show that urine excretion of B₁₂ is
raised in smokers, and that a high excretion of thiocyanate tends
to be associated with an increase in B₁₂ excretion and a rela-
tively low serum B₁₂ concentration. The association between
high thiocyanate excretion and low serum B₁₂ concentration,
which is especially marked in smokers, recalls that between
high serum cyanide concentration and low serum B₁₂ (Wilson
and Matthews, 1966); these two observations are probably
related. More than one hypothesis might be put forward to
explain these results. Thus it could be postulated that subjects
with relatively low serum B₁₂ concentrations have a reduced
ability to detoxicate cyanide by pathways involving this vitamin,
so that detoxication by the thiocyanate pathway is increased.
This would not, however, readily explain the association be-
 tween high thiocyanate excretion and high excretion of B₁₂.

Alternatively, the low serum B₁₂ concentration might reflect
B₁₂ depletion, possibly resulting from conversion of tissue
cobalamins to cyanocobalamin, a form relatively readily excreted
by the kidney (Nyberg, Saarini, and Gräsbek, 1961; Samson,
Yeh, and Chow, 1961; Glass, Skeggs, Lee, Jones, and Hardy,
1962; Okuda and Tantengco, 1962). Though chromatography
of serum B₁₂ in smokers (Lindstrand et al., 1966) showed only
small or moderate amounts of cyanocobalamin in some of the
group, it did not exclude the possibility that a minor degree of
conversion occurred in all. However, the increment in B₁₂ excretion associated with smoking (mean 0.021 μg./day, maxi-
 mum probably about 0.1 μg./day—Fig. 1) is so small in relation
to the amount probably absorbed daily (2–5 μg.) and to the liver stores (about 2,000 μg.) that it would seem unlikely that appreciable depletion could be caused in healthy people by this
means. This consideration, together with the very poor cor-
relation between serum B₁₂ and urine B₁₂ excretion, suggests
that some factor other than increased renal excretion of B₁₂
must operate to produce the relation between high thiocyanate
excretion and low serum B₁₂ concentration. It is possible that
high plasma cyanide concentrations disturb the equilibrium
between serum and urine B₁₂.

At the moment the main significance of this work is that it
shows further definite, if unexplained, interrelationships be-
tween smoking, cyanide metabolism, and bodily handling of
vitamin B₁₂, and gives further support to the idea that high
loads of cyanide might produce derangements of B₁₂ metabo-
limism. The effects of smoking are slight in healthy subjects,
but in patients already in marginal B₁₂ balance they might become
significant.

**Summary**

In view of evidence suggesting that there is a connexion be-
tween the metabolism of vitamin B₁₂ and that of cyanide,
and that smoking, which is associated with a high cyanide
intake, may disturb the metabolism of B₁₂; serum B₁₂, urine
B₁₂ excretion, and urine thiocyanate excretion (an index of
cyanide detoxication) have been measured in healthy smokers
and non-smokers.

The results show that urine B₁₂ excretion is raised in smokers
and that a high thiocyanate excretion is associated with an
increase in B₁₂ excretion and a relatively low serum B₁₂ con-
centration. The increase in B₁₂ excretion seems insufficient to
account for the reduction in serum B₁₂ concentration, which
may be the result of disturbance of the equilibrium between
serum and tissue B₁₂ by high plasma cyanide concentrations.
The work supports the idea that a high cyanide intake might
produce derangements of B₁₂ metabolism.

The work was supported by a grant from the Wellcome Trust.
