staff and patients, breaking down initial hostility and lack of understanding and the division between "them" and "us." There was a remarkable absence of disturbances and of demand for sedatives. Of interest was the request by discharged prisoners to be allowed to visit the unit after discharge and the marked change in attitude of the disciplinary officers.

Clearly such an inpatient unit, whether in prison or in hospital, can be no more than an initiation programme; its success must stand or fall on the planned aftercare and community service. The planning of such an aftercare programme, involving also the unit staff, was in progress when unfortunately, owing to administrative problems—namely, the current shortage of prison officers—the therapeutic programme had to be curtailed, one hopes only temporarily. In the view of staff and patients, who all bitterly regretted the interruption of the work, the "experiment" has undoubtedly been successful, largely owing to the enthusiasm and dedication of the prison officers. It has indicated the feasibility of setting up a closely-knit community with a therapeutic atmosphere even within the confines of a prison. For those addicts who land in prison (and one may hope that their numbers will gradually decrease) the therapeutic approach certainly seems to be much more promising than other approaches in current use, and in my own view deserves further trials in other selected prisons under the supervision of interested staff.

The above is the personal view of the writer only, and is not necessarily the view of the Home Office or its Prison Department.

Tenckhoff Catheter for Long-term Peritoneal Dialysis

Sir,—In reference to the paper by Dr. P. G. Lankisch and others (22 December, p. 712), we would like to make the following comments:

To date we have employed the indwelling Tenckhoff catheter in 13 patients treated by long-term peritoneal dialysis. Dialysis was initially carried out with manual exchange of 2-litre bottles of dialysate, similar to the procedure reported by Dr. Lankisch and his colleagues. Subsequently we have used a closed automated dialyse delivery system.

Episodes of peritonitis were readily managed by continuous peritoneal dialysis for 6-10 days using fluid containing the appropriate antibiotic.

These observations indicate that long-term peritoneal dialysis has a place in the management of terminal renal failure. It is already being used in patients with medical contraindications to haemodialysis, those lacking vascular access, and as an alternative to haemodialysis in hospital for patients who cannot be trained for haemodialysis at home. In the last group home peritoneal dialysis may provide better rehabilitation as it can easily be performed at night during sleep; also, it is less expensive than haemodialysis carried out in a centre.—We are, etc.

Tenckhoff Catheter for Long-term Peritoneal Dialysis

SIR,—Our experience with the use of the Tenckhoff catheter in chronic peritoneal dialysis is significantly different from that of Dr. P. G. Lankisch and others (22 December, p. 712).

During the past three years we have used 78 catheters in 66 patients. In 16 cases the catheter was obstructed after periods varying from 0-5 to 14 months (average 6 months). In 24 patients the catheter is still functioning after periods of 2-35-65 months (average 11-2 months). In the remainder the catheter was still functioning after an average period of seven months (0-27 months) when peritoneal dialysis was discontinued. Nine patients have been carrying out their peritoneal dialysis at home, using an automatic cycle operated on a machine for 4 hours each night. During the three-year period a total of 5,067 dialyses were performed. Ascitic fluid, if present, or a sample of the first effluent was sent for culture on each dialysis. Positive cultures were obtained in 40 cases (80%) and clinical peritonitis developed in 14 (25%). Whenever the catheter is obstructed because of peritonitis we do not change the patient to haemodialysis, but instead we continue dialysis, using the temporary catheter and the Dean prosthesis, until all signs of infection clear and then we replace the catheter.1 Fourteen patients received a kidney transplant and the catheter was used in the post-transplant period, if it was necessary, without any complication.

In contrast to the conclusions of Dr. Lankisch and his colleagues, we think that the permanent Tenckhoff catheter is ideal for chronic peritoneal dialysis. It can be used for long periods in patients awaiting renal transplantation. We do not use it in patients with borderline renal failure or patients on haemodialysis with complications who require short-term peritoneal dialysis. In these two groups we use the temporary catheter and the Dean prosthesis as we have described elsewhere.2 Finally, we have noticed that many catheters function satisfactorily even if there is radiological evidence of malfunction.

Battering: Dangers of a Backlash

SIR,—I share the concern of Dr. J. W. Woodward (9 March, p. 452) about the possible harmful effects of the police in the investigation of suspected cases of baby battering. The following case report illustrates the need for restraint and for close liaison between all interested parties.

A 2-year-old girl was brought to the attention of the social worker by her parents. The baby was of average birthweight 3.75 kgm. She was receiving 2% dextrose and saline solution 20 ml per 6 hours. She had been born at home some weeks before the date of admission. She had already been in hospital for 45 days. She was born at home, and no medical advice was sought. When examined she had a number of scald marks on her body.

The parents' home had previously been visited by the local police, who had found the house unsatisfactory for the baby's welfare and had considered it possible that the child was being neglected. She had been admitted to hospital 4 days after birth, having been born at home and cried only once. On examination it was found that she had a number of scald marks on her body.

When admitted to hospital she had a number of scald marks on her body. A number of mothers had subsequently been visited by the police, who found that the house was unsatisfactory for the baby's welfare and had considered it possible that the child was being neglected. She had been admitted to hospital 4 days after birth, having been born at home and cried only once. On examination it was found that she had a number of scald marks on her body.

Whether the child suffered from neglect or abuse is not known, but the parents did not express any concern about her welfare. The child was discharged 6 weeks after admission and was given follow-up until the age of 1 year. The child was discharged 6 weeks after admission and was given follow-up until the age of 1 year.

The child was discharged 6 weeks after admission and was given follow-up until the age of 1 year. The child was discharged 6 weeks after admission and was given follow-up until the age of 1 year.
eventually lead to a backlash which will destroy confidence and the necessary need for vigilance and referral of suspected cases of the syndrome. From its nature, this confidence can be built up only slowly, after years of painstaking work, but will be rapidly lost by a few injures.—I am, etc.,

Unusual Complication of Use of Sengstaken-Blakemore Tube

Sir,—We present, below, a previously undescribed hazard of the use of the Sengstaken-Blakemore tube.

The patient, a 55-year-old male alcoholic who presented with bleeding oesophageal varices. During the course of management a Sengstaken-Blakemore tube was passed and inflated with a Gastrografin and saline solution.1 The position of the tube was checked radiologically.

Despite sedation the patient was restless and succeeded in pulling the tube so that the oesophageal balloon was partly out of his mouth. The oesophageal balloon was immediately deflated, but no Gastrografin could be aspirated from the gastric balloon. The tube was passed back to the stomach and restored to the position. An x-ray (Fig. 1) showed the gastric balloon still inflated and in position, but the distance between it and the now malpositioned oesophageal balloon showed that the patient's sudden action had pulled the gastric balloon a considerable distance down the tube. Gastrografin injected via the gastric balloon's filling lumen did not increase the balloon's size, nor could it be reaspirated, showing that the balloon had been disconnected from its filling lumen.

Later the patient again pulled on the tube and, despite the inflation of the gastric balloon, he succeeded in extracting it, fortunately without damage to the oesophagus. Fig. 2 shows that the gastric balloon had now been forced to the tip of the Sengstaken-Blakemore tube. Its original position is revealed by the two holes of the filling lumen just below the oesophageal balloon.

This case illustrates that the gastric balloon of the Sengstaken-Blakemore tube can be forced away from its filling lumen to a position where it can be neither filled nor deflated. This was done in this case by a restless patient, but there is a danger of the same complication arising from traction applied therapeutically to the tube—a procedure criticized on other grounds by Pitcher.2 This is potentially dangerous for in this situation there may be no way in which the gastric balloon can be safely removed without a laparotomy and gastrostomy.

To some extent the dangers of this complication may be minimized by light sedation, but too heavy sedation increases the risks of inhalation of secretions. The problem could be avoided by redesigning the tube with continuous rubber balloons on the lines of the Foley urinary catheter balloon.—We are, etc.,

Apathetic T-3 Toxocosis

Sir,—Drs. P. D. Fairclough and G. M. Besser (2 March, p. 364) rightly emphasize the occult nature of many cases of hyperthyroidism, be it due to thyroxine or triiodothyronine. Their patient is yet another example of the situation in which a prolonged period of ill health precedes a firm diagnosis of overt hyperthyroidism.

There is evidence that a prehyperoxic state exists. In elderly subjects, in whom the cardiovascular system is relatively vulnerable, symptoms and signs referable to the heart and circulation may be due to this form of occult hyperthyroidism. A similar syndrome may well arise with triiodothyronine, though chemically the diagnosis is even more difficult to establish, as Drs. Fairclough and Besser have shown.—I am, etc.,

Patients’ Attitudes to Medical Students in General Practice

Sir,—As a student I read with great interest Dr. H. J. Wright's observations (2 March, p. 372) and would like to add some of my own.

I have recently completed an initial course with a group practice in Manchester. Though this was apparently not recognized by its patients as a teaching practice, I very rarely felt that my presence was in any way resented by the patients. On the contrary, many expressed surprise that they might be expected to object (this discourse the small number of more senior patients who feared that their life-long doctor was being replaced by a young unknown, and whose fears were rapidly dispelled. Nevertheless, I would have considered the courteous and correct opening to any consultation to be to introduce those present, if necessary explaining the capacity in which they are present, and to ascertain whether the patient objects to their presence. I should have expected such practice to be a common, indeed natural procedure and was surprised that Dr. Wright thought it necessary to make such a recommendation.

My experience and that of other students, though somewhat limited, indicates that the manner of introduction may have a considerable effect on acceptance by the patient. The term “medical student” implies that the patient is being used as a teaching object, an idea which the presence of two or more students may potentiate, and any such feeling might become a barrier to doctor-patient rapport. The patient-doctor relationship is more personal in general practice than in hospital and therefore to allow the presence of a student (which included an even greater privilege granted by the patient. I believe that the presence of more than one student is an abuse of this privilege.

The introduction of the student as a “student doctor” or, with a little poetic licence, a “young doctor,” though mean- less terms, considerably aided acceptance by the patient and also helped to encourage participation by the student. While I understand the guise of a “young doctor from the Infirmary” my presence was not objected to during consultation or physical examination, nor indeed was my examination of the patient (which included an internal examination where indicated). The only occasions on which I encountered uneasiness involved patients with psychosocial problems wishing to discuss them with their own doctor; I believe such a case was due to intrusion by another individual rather than specific objection to a student. In such a situation I found it necessary to withdraw and become a very passive observer to leave the consulting room altogether.—I am, etc.,
