Immediate plasma renin response to propranolol: differentiation between essential and renal hypertension

FALKO SKRABAL, WANDA CZAYKOWSKA, PETER DITTRICH, HERBERT BRAUNSTEINER

British Medical Journal, 1976, 2, 144-147

Summary

The immediate short-term effect on plasma renin activity of intravenous injection of propranolol was studied in 31 normal subjects and 166 hypertensive patients. In patients with essential hypertension and normal subjects plasma renin activity fell considerably within 15 minutes; the fall was directly proportional to initial plasma renin levels. In contrast, in patients with renal hypertension the fall was much less pronounced or totally absent. These differences in response to propranolol provide, though presently only on a group basis, a biochemical means of differentiating between patients with renal hypertension and those with essential hypertension. The observations also indicate that, unlike normal subjects and patients with essential hypertension, in patients with renal hypertension sympathetic activity plays no part in the control of basal plasma renin levels.

Introduction

Precision in endocrine diagnosis depends on the ability to measure all components of the feedback loops controlling hormone secretion.1 Nevertheless, renin levels in hypertensive patients are commonly still being interpreted without consideration of renal perfusion pressure, sodium concentration at the macula densa, or sympathetic tone at the juxtaglomerular apparatus, these probably being the main factors controlling renal renin release.2 None of the components of the feedback loops by which renin secretion is controlled is easily measurable in clinical practice. In an attempt to quantify sympathetic tone at the juxtaglomerular apparatus we have taken the immediate effect of acute beta-receptor blockade on basal plasma renin activity (PRA) as an indication of the extent to which renin release under basal conditions is mediated by the sympathovagal nervous system. A preliminary account of part of this work has been published.3

Patients and methods

We studied (a) 31 normal volunteers (19 female and 12 male hospital employers), (b) 102 patients (61 women) with stable benign essential hypertension (WHO stage 1 and 2), (c) 58 patients (30 women) with well-established renal hypertension of comparable duration and severity caused by chronic parenchymatous renal disease, and (d) six patients (two women) on chronic intermittent haemodialysis with hypertension of terminal renal failure.

Clinical details of the subjects are given in table I. Essential hypertension was diagnosed only after secondary forms of hypertension had been excluded by the usual diagnostic tests, which included urine analysis, blood chemistry, intravenous rapid-sequence

**Results**

The means (± SD) of basal and post-propranolol values of PRA, pulse rate, and blood pressure are shown in Table I. Significant correlations between the different measurements are shown in Table II. Within the given range of 24-hour urinary sodium excretion no significant correlation between sodium excretion and PRA was observed in either normal or hypertensive subjects. The frequency distribution of basal PRA in normal subjects and in patients with essential and renal hypertension is shown in Fig 1. This figure includes the values of 11 normal subjects in whom only basal PRA measurements were available.

**Response of PRA to propranolol in normal subjects**—In normal subjects PRA decreased by up to 42% within 15 minutes (fig 2). The percentage decrease in PRA were significantly related to basal levels (see table II). PRA remained unchanged in six normal subjects after the administration of 0·9% saline. The response of PRA to propranolol in hypertensive patients—Fig 3 shows the response of PRA to intravenous propranolol in patients with stable essential and renal hypertension, the subjects again being grouped according to their basal level of PRA. PRA fell significantly after propranolol in those patients with essential hypertension whose basal PRA was greater than 100 ng angiotensin I/1/hour, the percentage decrease again being related to basal PRA (table II). In contrast, the fall in PRA after propranolol in patients with renal hypertension was

uniformly less pronounced or absent. There was no correlation between basal PRA and the magnitude of decrease after propranolol (table I).

The pulse rate after propranolol decreased similarly in all subjects investigated; blood pressures did not change appreciably in any of the groups (table I).

Discussion

Propranolol inhibits the rise in PRA induced by orthostasis or by acute or chronic administration of diuretics in normal subjects and in patients with essential hypertension. The present study shows that propranolol also acutely lowers the previously unstimulated "basal" PRA after supine bed rest.

Since it is accepted that the fall in PRA after acute administration of propranolol is due to the inhibition of renin release,13,14 the magnitude of the decrease of PRA in our experiments seems to depend on two factors: the disappearance rate of renin activity from the circulation; and the extent to which basal release of renin is mediated by sympathetic tone. Given a half life of PRA of between 10 and 15 minutes,11,12 the fall in PRA should not exceed 50% after 15 minutes, even if PRA after supine rest were maintained solely by sympathetic activity. The maximum fall in PRA of between 50 and 60% observed in our study agrees with this. The highly significant correlation between basal PRA levels and the magnitude of decrease after propranolol suggests that sympathetic tone (sympathetic renal nerve activity or the level of circulating catecholamines, or both) is a major determinant of basal PRA in normal subjects as well as in patients with stable essential hypertension. No correlation has been observed between plasma noradrenaline levels and PRA;11 since, however, plasma noradrenaline has not been shown to reflect the total sympathetic input to the kidney, our interpretation is still valid.

Since the rate of fall in PRA after propranolol in patients with "high-renin" essential hypertension approximates to the maximal possible decrease, taking into account the half life of PRA, high basal PRA in benign essential hypertension may be maintained by increased sympathetic tone. This may explain the better hypotensive effect of propranolol in patients with high renin levels.17,18

Since we could not show any substantial fall in PRA after propranolol in patients with renal hypertension even after prolonged intervals,11 it seems that an impaired removal of PRA from the circulation19,20 is not the major explanation for the difference in response of PRA to propranolol between those with essential and those with renal hypertension. Furthermore, there is no evidence of a generally impaired responsiveness of the sympathetic nervous system in patients with renal hypertension.

The effect of propranolol on the cardiac beta-receptors seems to have been comparable in normal subjects and in patients with essential and renal hypertension, as judged by the similar decreases in pulse rate in the three groups (table I). Hence basal PRA in patients with renal hypertension seems to be maintained largely by factors other than sympathetic tone. The reduced renal perfusion, common to all patients with renal hypertension, might indicate that the renal baroreceptors are responsible for mediating renin release.

One of the critical questions that arise from this study is whether the patients with benign essential hypertension had secondary hypertensive renal damage, which might have obscured any differences between essential and renal hypertension. Since the progressive renal abnormality produced by long-standing hypertension apparently results in "low-renin" hypertension,21,22 patients with long-standing essential hypertension should be found in the low-renin group, where no difference in the plasma renin response between essential and renal hypertension was observed. This is confirmed by the significant negative correlations between age, known duration of hypertension, and PRA observed in this series (table II). If patients with more advanced essential hypertension, in whom the onset of renal failure might be associated with a final rise in PRA again,23 had been included in our study we would not have expected to observe a difference between such patients and those with renal hypertension.

Plasma renin measurements in patients with essential and renal hypertension give values which range from low to very high levels (fig 1) and there is nothing to suggest that these two types of hypertension can be differentiated by measuring basal PRA alone. Nevertheless, the present study shows that on a group basis the immediate renin response to propranolol differentiates between patients with essential hypertension and those with renal hypertension. This differentiation may become diagnostically useful, for instance by optimising the time interval between sampling or by simultaneous consideration of the other components of the feedback loops controlling renin secretion.

Enhanced drug metabolism in cigarette smokers

PRUE HART, G C FARRELL, W G E COOKSLEY, L W POWELL

British Medical Journal, 1976, 2, 147-149

Summary
The effect of cigarette smoking on salivary antipyrine disappearance rate, and as an index of hepatic drug metabolism, was studied in 42 healthy subjects. Antipyrine is metabolised almost completely by the liver.1 Although a recent study has provided more direct evidence that smoking stimulates drug metabolism by showing increased antipyrine clearance rates in smokers,4 these results varied considerably according to the age and other characteristics of the patients and could not be attributed solely to cigarette smoking. Smoking had no effect on diazepam plasma disappearance.3 Furthermore, although plasma levels of phenacetin are considerably lower in smokers than in non-smokers after comparable oral doses, there is no change in the plasma disappearance rate, and this probably reflects factors other than enhanced hepatic drug metabolism.8

We report here the results of a study designed to assess the effect of cigarette smoking on drug metabolism and to exclude both the influence of genetic variability and the effects of other environmental agents. This was done by studying a group of smokers before and after they had stopped smoking.

Introduction
Antipyrine is metabolised almost completely by the liver.2 5 Since it is not appreciably bound to plasma proteins and is distributed evenly throughout the total body water, the rate of antipyrine elimination provides a suitable method of assessing the activity of hepatic microsomal drug-oxidising enzymes. The wide variation in plasma antipyrine disappearance rates in normal subjects6 reflects the well-recognised phenomenon of considerable variation in interindividual rates of drug metabolism.

Patients and methods
The subjects studied were all healthy volunteers, some of whom were attending a hypnotherapy “stop-smoking” clinic. All gave informed consent. Subjects were excluded from the study if there was evidence of liver or renal disease or other disorders known to influence hepatic drug metabolism.7 8 Each volunteer was carefully questioned about his consumption of tobacco, alcohol, tea, and coffee and the use of pharmaceutical agents that may influence antipyrine half life. Those taking known hepatic microsomal enzyme-inducing drugs were excluded, as were those consuming alcohol in moderate amounts (<50 g ethanol per day). Most smokers smoked more than 20 cigarettes per day, but all consumed at least 11 cigarettes a day or 60-85 g (2-3 oz) tobacco a week. The non-smokers had not smoked at all for the previous six weeks. The average age of the smokers was 39 years (range 16-63 years) and that of the non-smokers 35 years (range 20-65 years). The subjects in each group were comparable in sex and consumption of coffee, tea, and alcohol.

Plasma or saliva antipyrine half lives, or both, were studied in 42 subjects (17 non-smokers and 25 smokers). Several people were studied more than once to assess intraindividual variability and any difference in apparent antipyrine half life due to different routes of drug administration (oral as opposed to intravenous) or method of sampling (saliva as opposed to plasma). Repeat studies were carried out in a manner identical to the initial studies. Eight smokers were also restudied about two months after they had stopped smoking. These subjects were then asked about changes in their life style other than stopping smoking.

An aqueous solution of antipyrine in a dose of 10 mg/kg body weight was either injected intravenously over 10 minutes or taken by mouth dissolved in 100 ml of orange juice. Five or more samples of venous blood (10 ml) or fresh saliva (5 ml) were collected at intervals during the next 30 hours. The antipyrine concentration of each sample was
