Discussion
This technique is simple to use, and most of the equipment is commercially available. It is acceptable to patients and enables impotence to be investigated in an ordinary, quiet hospital ward simply by admitting the patient for one or two nights. Direct measurements of penile erections correlate poorly with the presence of decreased libido or loss of morning erections and also with measurements of other aspects of peripheral or autonomic function. We believe that the technique represents a useful advance in the investigation of impotence, and we now use it routinely.

Two-thirds of our diabetic patients had nocturnal erections with an increase in penile circumference and a duration that were within the range shown by the healthy subjects. We cannot imagine an organic lesion that would lead to failure of erection during sexual activity and yet permit normal nocturnal erections, so probably in these patients the impotence was mainly caused by psychological factors. Six diabetics and one healthy subject showed a maximum increase in penile circumference of under 15 mm. The healthy subject, who claimed not to be impotent, was studied only once and on repeated tests might have shown more nocturnal activity, but the diabetics were each studied at least twice. Five of the diabetics complained of total impotence, and all had postural hypotension due to autonomic neuropathy; two also had Charcot’s joints. Impotence in these patients may therefore have had an organic basis.

We suggest that in most diabetic patients who complain of impotence the problem is psychological rather than organic, but why impotence should apparently be so common among diabetics is not clear. Possibly a period of ill health or poor diabetic control causes transient autonomic neuropathy producing reversible organic impotence that might be continued owing to psychological complications. We find that patients are reassured by knowing their impotence does not indicate organic disease, and after this reassurance, or after psychotherapy, some of our patients have reported improved sexual performance.

Praziquantel: a new schistosomicide against Schistosoma haematobium

J E McMAHON, N KOLSTRUP

British Medical Journal, 1979, 2, 1396-1399

Summary and conclusions
The effectiveness of the new schistosomicide praziquantel was assessed in African schoolchildren infected with Schistosoma haematobium. They were stratified according to the severity of their infection and were then randomly allocated to treatment with two single-dose regimens (30 and 40 mg/kg) and a split regimen of two doses of 20 mg/kg given four hours apart. All three regimens were highly effective and produced few side effects. Children who initially had very high pretreatment egg loads showed a poorer therapeutic response at all dose levels, and further investigations are necessary to find the optimum dose.

Because of its effectiveness in a single dose and lack of toxicity, praziquantel may prove to be the ideal schistosomicide.

Introduction
Praziquantel (Harnby 8440) is an isoquinoline-pyrazine derivative (2-cyclohexylcarboxyl-1,3,4,6,7,11b-hexahydro-2H-pyrazino (2,1-a)isoquinoline-4-one) (see figure). It has a broad antiparasitic effect, and is marketed as a veterinary taenicide under the trade name Droncit (Bayer). Clinical studies in man have shown that it is also effective in human tapeworm infestation.

There have been several reports on the pronounced biological activity of praziquantel against schistosomes in animals, and on its lack of toxicity in man, and on its effectiveness against the three main schistosome species parasitic in man. Schistosoma haematobi-
**Results**

The probable-cure rates and reduction in egg excretion in each of the groups (table I) showed that all treatment regimens were highly effective. Although group 3 (20 mg) had an apparently higher cure rate, the application of a t-test showed no significant difference between this regimen and those given to groups 1 and 2 (at one month's follow-up: \( r = 0.3666 (DF = 64) \) and \( 0.85496 (DF = 63) \) respectively).

Both the cure rate and the pronounced reduction in egg count at one month were maintained at three and six months' follow-up. At six months, as well as the 117 children who had three urine samples examined another 14 provided one or two specimens. Counts on these additional samples were also consistent with the pattern shown in the earlier follow-up examinations.

Analysis of results according to pretreatment egg loads (table II) showed that children with the heaviest infections (stratum III) had the lowest cure rate. But even in stratum III there was a considerable reduction in the number of children infected. The child with the most unfavourable parasitological response still showed an 89-8% reduction in egg excretion.

**Side effects**—No side effects attributable to the drug or related to intensity of infection occurred on any drug regimen. There were no significant effects on respiration, pulse rate, or blood pressure. Complaints of nausea, abdominal pain, weakness, headache, dizziness, tiredness, and pain in the limbs are relatively common in the schoolchildren in this area, and they occurred with equal frequency both before and after treatment and in treated and placebo groups (table III). Seventeen children failed to report for clinical examination 24 hours after treatment. All were traced and found to be working in the rice fields.

**Discussion**

The introduction of a drug combining effectiveness and lack of toxicity on oral administration of a single dose represents a

major advance in the treatment of schistosomiasis, both for individuals and potentially for mass chemotherapy in control schemes.

In the area where these investigations were conducted, where schistosomiasis is endemic, a comparative trial of niridazole (150 mg/kg administered over five days) and hycanthone (2.5 mg/kg single injection) was carried out. At two to three months’ follow-up niridazole and hycanthone treatment resulted in overall cure rates of 61.1% and 56.5%, respectively compared with a rate of 76.6% in this trial. Praziquantel also produced a greater reduction in egg load in patients who were not cured. Although the groups treated by these drugs were homogeneous in age, sex, and egg loads and the same techniques were used to evaluate drug effectiveness, transmission may vary greatly from year to year even in the same seasons. Because the level of transmission may affect the parasitological results after treatment, we recommend that a comparative trial of these three drugs should be conducted concurrently before conclusions are reached about the relative efficacy of each drug.

Preliminary investigations using praziquantel against S haematobium in adults have also shown a favourable parasitological response with low toxicity. Further investigations are needed to establish an optimum dose. The three treatment regimens that we used showed no toxic effects. The increased doses given to groups 2 and 3 did not affect the poorer therapeutic response in children with large egg loads (>501). But as there was no increase in toxicity at this dose (40 mg/kg) a further trial of even higher doses in people with high egg loads seems to be warranted.

Cure rates of schistosomicides are greatly influenced by pretreatment egg loads.

Our finding that children with very heavy infections (stratum III) had the lowest cure rate is similar to the results of a trial of niridazole against S mansoni. But people with increased intensities of infection do not always respond more poorly to treatment. For example, a group of adolescents gave a more favourable parasitological response to treatment with hycanthone than a group of children, even though their initial egg loads were much higher than those of the children. Here increased immunity in the older children may have influenced the result.

The excretion of a few viable eggs in 19 out of 96 pupils (19.8%) one month after praziquantel treatment may have been due to failure of the drug to kill some adult female schistosomes or to developing worms being present at the time of treatment. Schistosomicides tend to be ineffective against immature worms, and juvenile schistosomes in hamsters with S japonicum infections were less susceptible to praziquantel than mature forms.

During the past 20 years there have been many attempts to standardise methods for evaluating the effectiveness of schistosomicides. It was considered important to express the results of therapeutic trials as a reduction in the egg count because this is regarded as a far less variable measure of drug effectiveness than the cure rate.

At one month’s follow-up in our trial 48.4% of children in group 1, 33.3% of those in group 2, and 45.7% of those in group 3 were “definitely” cured—that is, they had stopped excreting eggs completely. Opaque and calcified eggs occur rarely in intestinal schistosomiasis. But in urinary schistosomiasis such eggs may be excreted for months, or even years, after successful treatment, and the probable-cure rate (nil or only non-viable eggs being excreted) is a truer reflection of the actual condition.

The mode of action of praziquantel is not known. In vitro drug concentrations as low as 0.3 μg/ml are rapidly schistosomicidal. No drug that is truly egg suppressant in the sense of inhibiting only the egg laying of the schistosome has yet been identified, and in our trial the maintenance of a favourable parasitological response after the first follow-up examination suggested that the drug killed female schistosomes rather than suppressed oviposition. As with many schistosomicides hepatic shift of adult schistosomes followed praziquantel treatment in baboons (Papio anubus) infected with S haematobium and vervet monkeys (Cercopithecus aethiops) infected with S japonicum; but histopathological studies showed that many worms also died in situ.

The control of schistosomiasis remains a major public health problem. In many areas where the disease is endemic children are the main group responsible for transmission. In the area where this trial was conducted children swim and play in water habitats containing the snail intermediate hosts (Bulinus (Physopsis) nasutus and B (P) globosus) of schistosomiasis. Before these children were treated they were potentially capable of extruding, into the habitats, millions of viable eggs daily. After treatment this potential was reduced to a few thousand per day. Treating populations with praziquantel before the transmission season combined with taking measures against the snail intermediate hosts might in certain epidemiological situations break transmission in a relatively short time.

Praziquantel, hycanthone, and metrifonate are the only schistosomicides known to be effective in a single-dose treatment against S haematobium in man. Praziquantel is more effective than metrifonate. It is less toxic than hycanthone, and in the regimen described here it seems to be more effective than the optimum dose of hycanthone. We therefore conclude that praziquantel, because of its effectiveness against the three main schistosomes harboured by humans, its low toxicity, and its ease of administration and stability, seems to be approaching the ideal schistosomicide.

We thank A Mwakanyamale, J Tao, and D Mwakijanga for technical help and Dr D Wegner for his advice and co-operation. Praziquantel was supplied by Bayer AG.

Boy or girl—parental choice?

G A DOVE, CAROL BLOW

British Medical Journal, 1979, 2, 1399-1400

Historical and archaeological evidence confirms that all ages and all societies have coped with the problem of selective preference for boys, and the need to limit their populations, by strategies that include simple infanticide, abortion, abstinence, adoption, and neglect. The practice of exposing alive the unexpected or unwanted child is a subject of considerable interest and controversy which recurs in the myths and legend of most, perhaps all, peoples.

The following case history reveals and examines this phenomenon and the controversy it caused, initially among medical students at a general practice seminar and later among the medical staff who became involved.

Case report

A 30-year-old married Englishwoman (an only child) pregnant for the sixth time (para 3+3) threatened to kill both herself and the child of this pregnancy if the child was another daughter. The problem was presented to the general practitioner by her husband (also English), whose dilemma was how to deal with his wife’s threat. The woman herself had agreed to the first two abortions and continued in the need for the third—her husband wanted to buy a car. All three abortions had occurred before the “normal” birth of their two live girls, both now under 5 years old.

At a subsequent interview between the general practitioner and the wife she admitted to her feelings and requested an amniocentesis to determine the sex of the child, and an abortion if the fetus was not male. It was thought that the husband, despite his obvious dilemma, might also wish for a boy and thus be colluding with his wife. Whatever happened, it seemed likely that the woman would continue to get pregnant until a male child was born to them, thus sterilisation or contraception was out of the question.

The patient was introduced by the general practitioner to a “sympathetic” gynaecologist, who, after consultation with his colleagues, agreed to have an amniocentesis performed providing the patient undertook psychiatric treatment. To this both husband and wife readily agreed. The result of the amniocentesis, performed at the 21st week of the pregnancy, showed that the fetus was female.

The prevailing medical opinion was that her request for an abortion on these grounds should be refused but that considerable support should be given to the continuation of the pregnancy together with an undefined offer of some help should a subsequent pregnancy occur.

She was delivered of a normal female child at 40 weeks by a caesarean section. Three months after the delivery mother and child are alive and well and the mother continues to receive psychiatric support.

Discussion

The demands that this woman and her family made on our medical expertise led us to question the basic social and biological factors which operate in our society and which provoked a seemingly intelligent woman to want to terminate a pregnancy for this reason. Furthermore, her demands led us to question her ability to care for her progeny of either sex now or in the future: do her live children require surrogate support? Nevertheless, the evidence is that she is an exemplary wife and mother.

A recent global review of the subject found that despite the emergence of female emancipation and the need to limit family size a preference for boys remains. In all communities “economic considerations for sex preference are minimal while psychological and emotional considerations have come to the fore”—that is, anxiety about not having sons is evident. The review concluded that sex preference simply reflects the roles women and men have in society and conflicts with the humanitarian notion that every child is a wanted child and it questioned the status of women in society. Milton Freeman in his comments on the prestige, ethos, and economics of the practice of infanticide in primitive Eskimos regarded it as an evaluation of adult sex roles rather than a primary means of population control.

One must ask the question whether this woman’s need for a son represented a similar interpretation of sex roles in our supposedly emancipated society or whether it was the surfacing of other primitive, complex feelings that men have about pregnancy and which should be looked for in counselling before and after termination of pregnancy and in antenatal care. It is interesting that such strong feelings, expressed by an articulate, aggressive woman who was diagnosed as requiring psychiatric care, were not only listened to but acted on.

New techniques for diagnosing fetal abnormality by amniocentesis may create entirely new attitudes. There is certainly
