Solvent abuse and the heart

The deliberate inhalation of volatile substances, usually halogenated or unsubstituted hydrocarbons, to obtain a “high” is common among teenage boys and causes important morbidity and mortality. Solvent abuse may cause both acute and chronic cardiotoxicity, and this issue carries three reports of serious cardiac problems associated with exposure to volatile hydrocarbons (pp 727 and 739).

In 1970 Bass reported an epidemic of sudden deaths associated with solvent sniffing in the United States. He proposed that these deaths were caused by an arrhythmia and suggested that volatile hydrocarbons might sensitize the heart to the arrhythmogenic effects of endogenous catecholamines. There is now much evidence to support this hypothesis. Firstly, solvent abuse has been followed by documented ventricular fibrillation. Secondly, sudden death related to solvent abuse has occurred often in circumstances associated with intense cardiac sympathetic stimulation—physical exertion, particularly running, and various forms of autoerotic behaviour. The case of myocardial infarction, possibly caused by coronary artery spasm, and ventricular fibrillation described by Cunningham et al (p 739) fits the same pattern. Thirdly, well controlled studies in dogs have shown that adrenaline given after many different inhaled volatile hydrocarbons may produce serious ventricular arrhythmias including ventricular fibrillation. Furthermore, ventricular tachycardia has been seen in conscious dogs subjected to a loud noise or made to run on a treadmill after inhaling volatile hydrocarbons. Hypoxia, hypokalaemia, and alcohol may all increase the risk of an arrhythmia after solvent abuse, and the cases described by McLeod et al (p 727) suggest that there may also be an adverse interaction with halothane.

Studies of acute toxicity have shown that inhaled volatile hydrocarbons can also induce bradyarrhythmias and hypotension; these observations were made, however, in animals under general anaesthesia and may not therefore be relevant to those who sniff glue or inhale from aerosol cans.

The relative toxicity of the many chemicals inhaled is not known, largely because we do not know the prevalence of abuse of each agent. Nevertheless, all of these substances may be cardiotoxic. Their effects on the heart are probably caused by non-specific physicochemical actions and seem to occur at doses similar to those that affect the central nervous system. This implies that any sniffer who obtains a “high” also runs the risk of developing an arrhythmia, particularly if he or she then exercises.

Drums begin to beat in the waiting list jungle

Radical change in medical practice is bound to be necessary to shorten the time patients wait for treatment and investigation in the National Health Service. Just last month the government allocated another £25m to help health authorities reduce their waiting lists (28 February, p 590), and last week saw surgeons and managers meeting together at the King’s Fund to discuss what should be done (p 783). If quicker is better—and in some cases present treatment delays mean no treatment—are doctors willing to alter the referral system and assist their patients to earlier treatment? Will general practitioners refer patients away from the local hospital and named consultant on to others who can see, diagnose, and treat more quickly? Can consultants be persuaded to send their patients on to colleagues within their specialty who can offer quicker treatment?

There is a practical difficulty. Despite modern communications, advances in technology, and the Körner reports on information systems in the NHS, there is no system within

Rhabdomyolysis, renal and hepatic damage, and various neurological, psychiatric, and metabolic syndromes have been attributed to habitual solvent abuse. Now Wiseman and Banim (p 739) and McLeod et al (p 727) report three cases of dilated cardiomyopathy associated with chronic solvent abuse or in one case heavy occupational exposure to 1,1-trichloroethane. Although there are one or two similar case reports, the evidence that volatile hydrocarbons may cause a dilated cardiomyopathy is still only anecdotal. Nevertheless, physicians should consider chronic solvent exposure when treating patients with dilated cardiomyopathy, and anaesthetists should be aware of the potential hazards of using halothane or similar agents in patients who may be solvent sniffers.
