Oral rehydration solution containing trisodium citrate for treating severe diarrhoea: controlled clinical trial

Ramendra N Mazumder, S K Nath, H Ashraf, F C Patra, A N Alam

Oral rehydration solutions are highly effective for treating most patients with dehydration due to diarrhoea. Early formulations contained glucose and three salts: sodium chloride, sodium bicarbonate, and potassium chloride. Subsequently, a formulation containing trisodium citrate dihydrate instead of sodium bicarbonate was shown to be more stable under high humidity and temperature conditions and equally effective in treating dehydration and acidosis due to diarrhoea; in one study of patients with cholera the severity of purging was significantly less and in another study there was a similar trend. In a randomised double blind trial we compared the two solutions.

Patients, methods, and results

We studied males aged 8-56 years with diarrhoea of less than 48 hours' duration and signs of severe dehydration who had not received any antibiotics. Fluid was replaced by intravenous acetate solutions over about four hours. A stool specimen was obtained to isolate diarrhoeal pathogens. After hydration patients were randomly assigned to receive either a citrate oral rehydration solution (n=90) or a bicarbonate solution (n=90). Packets were provided by the World Health Organisation in a randomised sequence bearing patient serial numbers; the randomisation code was kept with the organisation. The citrate solution (osmolality 311 mmol/l) contained trisodium citrate 10 mmol/l and the bicarbonate solution (331 mmol/l) contained sodium hydrogen carbonate 30 mmol/l. Both solutions looked identical and were provided at the bedside of patients, who drank freely until diarrhoea stopped; food was withheld for 24 hours.

The volume of stools, vomit, and urine and the amount of solution consumed were recorded every eight hours until the diarrhoea had stopped (that is, passage of the last liquid stool). Patients received tetracycline (50 mg/kg in 24 h with a maximum of 2 g/day) orally for 48 hours starting 24 hours after starting oral rehydration. Patients who became dehydrated during oral replacement were given rapid intravenous infusion followed by oral treatment. Data were analysed by the SPSS PC+ package and significance of outcome variables examined by the rank sum test.

Patients' age, sex, and severity of diarrhoea were similar in both groups. Vibrio cholerae and enterotoxigenic Escherichia coli were the two main pathogens isolated (88% of patients receiving citrate solution and 87% of those receiving bicarbonate solution). Seven patients (four receiving citrate and three bicarbonate) were excluded from the analysis because of absence of diarrhoea after starting treatment or incomplete stay, or both.

As the first 24 hours are most critical in cholera and diarrhoea due to E. coli we did evaluations within this period. The table shows that during the first 24 h of oral rehydration the stool volume was significantly (p=0.05) less by (11%) in those receiving citrate than in those receiving bicarbonate.

Discussion

Stool reduction with citrate solution may be related to enhanced absorption by enterocytes. The lower luminal osmolality of the citrate solution (311 mmol/l) than the bicarbonate solution (331 mmol/l) may have contributed. The total stool volume up to recovery was not, however, significantly different between groups. The intake of solution was significantly (p=0.01) less (by 18%) in those receiving citrate solution than in those receiving bicarbonate solution; this finding is compatible with the reduced purging in those receiving citrate solution.

Our patients had mild acidosis (table) before starting treatment; after 24 h carbon dioxide concentrations were normal, showing the ability of trisodium citrate in oral solution to provide base and correct acidosis. Serum concentrations of other electrolytes were similar and normal after 24 h. Forty six patients (26%) became dehydrated and required short courses of intravenous infusion during oral replacement. Previous studies show that despite antibiotic treatment from the beginning, 16% of patients with cholera treated with oral solutions alone may need short courses of intravenous infusions. No significant difference between the two groups was observed in duration of diarrhoea.

We conclude that citrate oral rehydration solution is not only highly stable with a long shelf life but also reduces fluid loss and oral fluid requirements in patients with acute diarrhoea. It is as effective as bicarbonate solution in preventing acid-base abnormalities.

## Smoking and blood pressure in 15 year olds in Dunedin, New Zealand

Ian M George, Sheila Williams, Warren R Stanton, Phil A Silva

Among the immediate effects of inhaling cigarette smoke is a rise in heart rate and blood pressure as a result of the action of nicotine at a number of sites effecting neurocardiovascular control. Many studies— for example, that by Simpson et al— have found lower average systolic and diastolic blood pressures in adults who smoked than in non-smokers.

**Methods and results**

The sample and techniques of measurement used in this study have been detailed elsewhere. Children born between 1 April 1972 and 31 March 1973 in Dunedin were seen at intervals of two years. Sample selection, attrition, and changes in characteristics with time have been described by Silva. Measures of smoking, cardiovascular fitness, exercise tolerance, and body size were available for 839 children at age 15.

Blood pressures were obtained at rest and during a standard six minute submaximal cycle ergometer test: before exercise, while seated on the cycle at rest; immediately after the sixth minute of exercise; and after five minutes’ recovery.

Smoking histories were obtained at ages 11 and 15. Blood pressures at age 15 were compared for five groups, defined in terms of their smoking history at age 15: those who had never smoked, who had smoked infrequently but not in the past two years, had smoked infrequently in the past two years, had smoked occasionally in the past four weeks, and smoked daily. Analyses of variance and covariance were used.

The table shows means for various systolic blood pressure measures. There was a significant difference among the smoking groups for both unadjusted and adjusted systolic blood pressure at rest and before exercise. After adjustment for height, weight, and sex the difference in blood pressure between the non-smoking group and the group who smoked daily was 4.3 (95% confidence interval 1.8 to 6.8) mm Hg for resting systolic blood pressure and 4.8 (2.1 to 7.5) mm Hg for systolic blood pressure before exercise.

### Means and adjusted means for systolic blood pressure (mm Hg) measured at age 15 in terms of smoking history at age 15

Comment

Explanations suggested for lower interval blood pressure in adult smokers have included lower weight, differences in alcohol consumption, relief of stress by smoking, or a lower "sympathetic tone." Some researchers have even suggested that smokers with hypertension die younger than non-smokers, leaving a population of smokers with lower than average blood pressures.

Our results were similar in direction and magnitude to those found in adult smokers and suggest an effect at least on systolic blood pressure, evident even in young occasional smokers. This effect was not apparent during exercise, suggesting it can be overcome by increased catecholamine release. That the differences had not been evident four years earlier suggests that they were caused by smoking.

Selective mortality does not apply at age 15 and the effect of body size has been adjusted for in the present study. A reduction in sympathetic activity evident in the intervals between smoking seems the only tenable explanation.
