minimise the risk of personal and family breakdown. New service models will require evaluation.

We thank all families who kindly participated in the study. We are grateful to the Housing Department of the Birmingham City Council, Mrs Daphne Agnew, the staff of the seven hostels, the head teachers of the schools involved in the selection of the comparison sample, and Mr Saeed Haque for the statistical advice.

Contributors: PV participated in the formulation of the study hypothesis, research design, data analysis and writing of the paper and is the guarantor of the paper. EG completed data collection and participated in data analysis and writing of the paper. SC participated in the formulation of the study hypothesis, research design, data analysis, and writing of the paper.

Funding: Nuffield Foundation. Conflict of interest: None.

Rate of recurrent collapse after vaccination with whole cell pertussis vaccine: follow up study

Patricia E Vermeer-de Bondt, Jerry Labadie, Hans C Rümke

Whole cell vaccines against pertussis can induce a hypnotic-hyporesponsive episode or shock-like syndrome (collapse) in children, but this may also occur with diphtheria and tetanus vaccines, acellular pertussis vaccine, and without vaccination. Two prospective studies estimated that the rate of collapse after vaccination was considerable (15 out of 35 284 and 9 out of 286). The only follow up study, which assessed a small series, was inconclusive about sequelae.

Comparing the rates of collapse between countries poses problems because of differences in vaccination schedules and vaccines and in the way adverse reactions are monitored and symptoms reported. Moreover, case definitions are inconsistent.

Although the rate of recurrent collapse after whole cell pertussis vaccine has not been studied, for over 30 years repeat doses of vaccine have been contraindicated in children who experience a collapse reaction. Before 1993, in both the Netherlands and the United States children who had had a collapse reaction after vaccination with whole cell pertussis were not given a repeat dose. This contraindication still applies in the Netherlands, although most children are given further doses. We measured the numbers of cases of collapse in children after vaccination with whole cell pertussis vaccine in the Netherlands in 1994 and followed up all cases who were reported after their first dose.

Subjects, methods, and results

In the Netherlands over 99% of childhood vaccines are administered routinely by specialised staff within a child health clinic. All vaccinations are registered in provincial databases, so that data are accessible to medical staff if a child changes address. In 1962 an enhanced passive surveillance system for monitoring adverse events following vaccinations, with a 24 hour telephone service, was instigated. Some degree of underreporting is inevitable, but it seems to be limited and not biased against collapse (our laboratory's year report, 1994). Collapse is defined as sudden loss of muscle tone, pallor, and unresponsiveness. Sometimes symptoms are incomplete or atypical. When only one of the symptoms is present, the event is logged as an unspecified minor illness and not collapse.

In 1994, 712 adverse events were reported to the surveillance system, 587 after combined vaccination against diphtheria, tetanus, pertussis, and poliomyelitis (DTP-IPV vaccine) and Haemophilus influenzae type B (Hib-PRP-T vaccine). (The adverse events from H influenzae type B vaccine are infrequent and mild and not dealt with here.) After verification of symptoms we diagnosed 134 collapses (table).

In 1996 we followed up the 105 children with collapse reported after their first vaccinations. Detailed...
Patients, methods, and results

Calculations of sample size indicated that 21 patients per group would be needed to show a reliable difference at the 5% level of significance. The participants were 93 consecutive patients who had been referred to the prosthetic rehabilitation clinic and were aged 34-91 (mean 65) years; 54 were men. Time since amputation was 1-58 (9.7) years. Sixty patients had had a leg amputated for vascular illness, including diabetes, 10 of them losing both legs. Twenty four patients had lost a leg and nine an arm because of trauma. RSH obtained a clinical history including information about previous and concurrent medical and psychiatric problems. Phantom pain was assessed with the short form McGill pain questionnaire, the patients endorsing all words describing their phantom pain, if present. KF, who was blind to the pain report, then assessed them with the hospital anxiety and depression scale.

Phantom pain, anxiety, depression, and their relation in consecutive patients with amputated limbs: case reports

K Fisher, R S Hanspal

PHANTOM PAIN

Katz and Melzack, in 1975, suggested that emotional factors are influential in patients' experience of prolonged pain in a phantom limb after amputation and concluded that this may be prevented if patients are encouraged to express grief over their loss. However, Katz and Melzack found no significant difference in standardised tests of psychological dysfunction between patients who experienced phantom pain and those who did not. They concluded that the pain is more likely to vary with the experience of preamputation pain, even retaining many of its characteristics. A review of the literature on measures used to diagnose psychopathology found that many measures include items that confound emotional distress with the physical disorder and thus overestimate it. We investigated whether people who had had arms or legs amputated experienced emotional distress, and the relation between the distress and pain, using standardised screening techniques designed for patients with physical illness.
