Cohort study of bacterial species causing urinary tract infection and urinary tract abnormalities in children

Olli Honkinen, Olli-Pekka Lehtonen, Olli Ruuskanen, Pentti Huovinen, Jussi Mertsola

Children with urinary tract infection often have anatomical or functional abnormalities in their urinary tract. Imaging studies are therefore recommended, especially for young children, after the first urinary tract infection. There is, however, considerable variation in clinical practice and some resistance to diagnostic imaging for childhood urinary tract infection. We conducted this study to find out whether an association exists between the bacterial species causing the first urinary tract infection and abnormal findings in subsequent imaging studies.

Patients, methods, and results

We examined retrospectively the hospital records of all children with a positive urine culture from a sample obtained by suprapubic aspiration (any growth) or catheterisation (growth of at least 10^5 colony forming units/ml) during January 1980 to December 1994. Asymptomatic children and those who had been in hospital for more than 2 days before the specimen was obtained were excluded. Children with proved infection had intravenous pyelography (1980-3) or ultrasonography (1984-94) plus voiding cystourethrography (radiographic in boys and nuclear in girls) 1-2 months after the acute infection.

We identified 1237 positive urine samples. Of these, 942 (76%) were obtained by suprapubic aspiration and 295 (24%) by bladder catheterisation. There were 982 (79%) cultures positive for Escherichia coli, 66 (5.3%) for Enterococcus sp, 55 (4.4%) for Klebsiella sp, 47 (3.8%) for coaguloase negative staphylococcus, 39 (3.2%) for Proteus sp, and 48 for other species. Of the 207 patients with enterococcal, klebsiella, coagulase negative staphylococcal, or proteus infections, hospital records were available for 201. Forty one patients were excluded (20 had asymptomatic bacteruria, seven had chronic urinary problems such as neurogenic bladder, and in 14 cases one or both of the urinary tract imaging studies were lacking). The urinary tract infection was the first in 92 of the remaining 160 children with infections other than E coli.

We compared the results of these children with those of 92 age and sex matched children whose first urinary tract infection was caused by E coli. Student's t test was used to compare the mean serum C reactive protein values in the two groups. The frequency of abnormalities in the urinary tract was compared by Pearson's χ² test or Fisher's exact test if the number of expected observations was five or less in at least one cell.

Age, sex, imaging results, and operations in children according to cause of first urinary tract infection. Values are numbers (percentages) unless stated otherwise

(Accepted 28 October 1998)
The table shows the characteristics of the 184 patients and findings in the imaging studies. There were significantly more abnormalities among children with enterococcal, klebsiella, or coagulase negative staphylococcal infections than in children infected with E. coli. The rate of corrective surgical procedures was also substantially higher in these patients. Only two abnormalities were diagnosed in children with proteins infection.

Comment

Our results agree with earlier studies showing that about 80% of urinary tract infections are caused by E. coli and that vesicoureteral reflux is found in about a third of children with infections caused by E. coli. We also found that when the first infection was caused by klebsiella or enterococcus the rate of vesicoureteral reflux was almost double and that surgical procedures were four times more common in children with infections caused by these organisms than in those with infections caused by E. coli.

E. coli lacking putative virulence factors such as galgal specific adhesins are overrepresented in patients with pyelonephritis associated with vesicoureteral reflux. Similarly, in children with acute pyelonephritis, renal scarring is significantly more common in those infected with non-E. coli organisms and with E. coli strains that do not possess certain virulence determinants. The bacteria probably do not need special virulence properties if the host has an abnormality such as vesicoureteral reflex.

Contributors: OH, the principal investigator for the study, was involved in the data collection, documentation and analysis. O-PL and PH organised the collection and analysis of the microbiological data. OR initiated the research and participated with JM in the analysis and interpretation of the clinical data. The paper was written jointly by OH, O-PL and JM. OH and JM are guarantors of the study.

Severe ergotism associated with interaction between ritonavir and ergotamine

Lucas Lanzad, Thierry Buegin, Christian Jaccard, Philippe Eckert, Critical Care Division, Department of Internal Medicine (Service B), University Hospital, 1011 Lausanne, Switzerland

Ergotism is a severe complication of chronic abuse or acute intoxication with ergot derivatives. Occasional cases have been reported in patients taking usual doses of ergot combined with drugs that interact with it. We report a case of severe ergotism associated with the anti-HIV drug ritonavir.

A woman aged 28 who was positive for HIV infection was treated with anti-HIV therapy: stavudine (40 mg/12 h), didanosine (290 mg/12 h), and ritonavir (600 mg/12 h). She also received fluoxetine (20 mg/24 h) for depressed mood. Five days before admission she had begun to take a combination drug (0.5 mg ergotamine tartrate, 0.2 mg belladonna extract, and 20 mg phenobarbital) twice daily for gastric discomfort. On the day before admission she developed painful sensations in both legs. Despite the addition of intravenous sodium nitroprusside, heparin, and morphine for spasms affecting the aorta and the femoral and humeral arteries; distal pulses were absent. Treatment with intravenous sodium nitroprusside, belladonna, and nitroprusside was started. Peridural anaesthesia was needed for intractable pain. After 3 days she developed cyanosis and oedema in both legs. Despite the addition of intravenous nifedipine, ioprost, and nitrates, she developed bilateral gangrene of the toes, necessitating transmetatarsal amputation 5 weeks later.

This patient developed severe ergotism after taking 3 mg ergotamine over 5 days, a low dose in terms of the recommended safe dosage of ergot (up to 6 mg a day or 10 mg a week during chronic administration). We speculate that an interaction between ritonavir and ergotamine was responsible for this case. Indeed, ritonavir is a potent inhibitor of cytochrome P-450 isoenzymes, mainly CYP3A4, which is responsible for the metabolism of ergot. Thus, ergot concentrations probably increased to toxic amounts in our patient because ritonavir inhibited ergotamine metabolism. Fluoxetine, another inhibitor of cytochromes, might also have played some part by blocking supplementary metabolic pathways. This interaction between ergot derivatives and ritonavir has been described in the technical information provided by the manufacturer, and another case of ergotism has been reported in a patient with AIDS who received both ritonavir and ergotamine.

Doctors should be aware of this harmful interaction, and any administration of ergot alkaloids should be discontinued when ritonavir treatment is started in patients with HIV infection.
