Folate and vitamin B-12 and risk of fatal cardiovascular disease: cohort study from Busselton, Western Australia

Joseph Hung, John P Beilby, Matthew W Knuiman, Mark Divitini

Abstract

Objective To test the hypothesis that the incidence of fatal coronary heart disease and cardiovascular disease in a general population is related to serum and red cell folate and vitamin B-12 concentrations.

Design Cohort study with follow up of 29 years.

Setting Busselton, Western Australia.

Participants 1419 men and 1531 women aged 20 to 90 years, who were alive more than three years after their participation in the 1969 Busselton health survey. 2314 (78.4%) had no cardiovascular disease at the initial survey.

Main outcome measures Hazard ratios for fatal coronary heart disease and cardiovascular disease in men and women according to baseline concentrations of serum and red cell folate and serum vitamin B-12.

Results 213 men and 159 women died from coronary heart disease, and 342 men and 302 women died from cardiovascular disease. Serum and red cell folate concentrations showed a moderate positive correlation ($r=0.26, P<0.001$) but otherwise serum and red cell folate and serum B-12 concentrations were not strongly correlated with each other or with other standard risk factors. After age and standard risk factors were adjusted for, there was no independent association between folate and B-12 concentrations and death from coronary heart disease or cardiovascular disease in the full cohort or the subcohort with no cardiovascular disease at baseline. The multivariate adjusted hazard ratio for death from cardiovascular disease in the lowest versus the highest category of red cell folate concentration was 1.05 (95% confidence interval 0.77 to 1.43) in men and 1.10 (0.81 to 1.51) in women.

Conclusions These findings do not support the hypothesis that lower folate and B-12 concentrations increase the risk of fatal cardiovascular disease in a general population. The routine use of these vitamins for preventing cardiovascular disease should await evidence from clinical trials.

Introduction

Epidemiological studies have shown that moderate hyperhomocysteinaemia is an independent risk factor for coronary, cerebral, and peripheral vascular disease. Randomised clinical trials have shown that low dose vitamin supplementation, particularly with folic acid, significantly lowers homocysteine concentrations. However, there are no clinical trial data that prove that lowering homocysteine concentrations prevents deaths from cardiovascular disease or coronary heart disease.

Several secondary prevention trials testing folic acid are under way, but primary prevention trials are problematic because they require much larger sample sizes and longer follow up. Potential trials are also complicated by the widespread introduction of grains and foods fortified with folate and by increasing recommendations for the use of folic acid supplements in cardiac patients and the general population. In the absence of proof from prevention trials, it is useful to seek evidence that circulating or dietary levels of folate and vitamin B-6 and B-12 in the general population are related to incident cardiovascular disease. Prospective evidence linking these factors remains limited and inconsistent.

The purpose of this cohort study was to test the hypothesis that an increased incidence of fatal coronary heart disease and cardiovascular disease was related to lower concentrations of serum and red cell folate and serum vitamin B-12 in a community population.

Participants and methods

Busselton is a seaside town in Western Australia with a predominantly white population. Cross sectional health surveys of adults listed on the electoral roll (enrolment to vote is compulsory in Australia) were undertaken every three years from 1966 to 1981. This study is based on 1772 men and 1904 women aged 20 to 90 years who attended the 1969 survey, representing a 90% participation rate for the total adult population. The human research ethics committee, University of Western Australia, approved the study.

The methods of the surveys, including a detailed description of the study population, examination of participants, and laboratory methods have been described elsewhere. In summary, the participants were asked to complete a comprehensive health and lifestyle questionnaire and to undergo various measurements and tests. Sitting blood pressure was measured by mercury sphygmomanometer after five minutes' rest. Body mass index was derived as weight
(in kilograms) divided by the square of height (in metres). Details of smoking, alcohol consumption, diabetes, and use of antihypertensive drugs were obtained by questionnaire. Coronary heart disease was determined from the Rose questionnaire for angina and myocardial infarction and the electrocardiogram together with a self reported confirmation of a doctor’s diagnosis of heart disease. Serum cholesterol concentrations were determined from a fasting blood sample. Serum and red cell folate and serum vitamin B-12 concentrations were measured in fresh samples by using automated microbiological assay systems. The within-run coefficient of variation was 1.5% for paired measurements of folate for concentrations ranging from 1.9 to 17.0 µg/l.

Analysis of data
There were 1486 men and 1570 women available for analysis after we excluded pregnant women and those with missing values for primary risk factors or adjustment variables. Of these, 67 men and 39 women died within three years of the 1969 survey and have also been omitted, leaving a total of 1419 men and 1531 women for analysis.

1531 women. A total of 1115 men and 1201 women (78.4% of cohort) had no history of coronary heart disease, leg claudication, or stroke at initial survey and were considered free from cardiovascular disease. We analysed data from this subcohort separately.

The risk factors of primary interest were serum and red cell folate concentrations and serum B-12 concentration. We also included other baseline risk factors for cardiovascular disease in the multivariate analysis: age, systolic and diastolic blood pressure, body mass index, serum cholesterol concentration, white cell count, smoking, menopause (in women), treatment for diabetes, treatment for hypertension, alcohol intake, and history of coronary heart disease, stroke, or leg claudication.†

We used Cox proportional hazards regression analysis of survival to death or end of follow up to assess the influence of primary risk factors after adjustment for age only and also after adjustment for age and other risk factors.‡  † As the age adjusted and multivariate adjusted results were similar, only the multivariate results are reported. We did separate analyses for men and women and for the whole cohort and the subcohort who had no cardiovascular disease at baseline. Vitamin concentrations were examined as continuous variables and also in categories. We used log (base e) transformations of folate and B-12 concentrations as continuous variables because of skewed distributions. The categories were based on approximate quartiles for the entire study group, with the quartiles rounded and the same categories used for all groups analysed. The P values from the models that used the vitamin level as a continuous variable are presented as trend P values. Results from the models that used vitamin level as a categorical variable are reported as adjusted hazard ratios (relative risks) with 95% confidence intervals relative to the highest group. We also presented data as trend P values. Results from the models that used the quartiles rounded and the same categories used for all groups analysed. The P values from the models that used the quartiles rounded and the same categories used for all groups analysed.

We did separate analyses for men and women and for the whole cohort and the subcohort who had no cardiovascular disease at baseline. Results from the models that used vitamin level as a categorical variable are reported as adjusted hazard ratios (relative risks) with 95% confidence intervals relative to the highest group. We also did a survival analysis restricted to 15 years of follow up.

Results

Table 1 shows the baseline risk characteristics of the cohort. The average age was about 48 years and the risk factor characteristics are typical of population samples surveyed around that time. Serum folate and red cell folate concentrations showed a moderate positive correlation ($r=0.26; P<0.001$) but neither serum nor red cell folate and vitamin B-12 concentrations were correlated with each other or with other risk factors (data not shown).

After 29 years' follow up, 665 men and 537 women had died (excluding subjects who died within three years of initial survey). Death was due to cardiovascular disease in 342 men and 302 women and to coronary heart disease in 213 men and 159 women. In the subcohort of participants without cardiovascular disease, 475 men and 362 women had died; deaths were due to cardiovascular disease in 226 men and 187 women and to coronary heart disease in 131 men and 98 women.

Tables 2 and 3 show the multivariate adjusted hazard ratios for folate and vitamin B-12 in men and women in the full cohort. Among women in the subcohort without cardiovascular disease, there was a generally inverse association between serum folate concentrations and risk of death, but the only significant relative risk was for all cause mortality, and the trend P value was not significant at the 5% level. Among men in the subcohort without cardiovascular disease, the trend model suggested an unexpected positive association between serum folate concentration and risk of death from cardiovascular disease ($P=0.05$), but the categorical model showed no association. Further exploration revealed that a subgroup of 85 men (7% of the disease-free cohort)

with serum folate concentrations >9 µg/l had about double the risk of death from cardiovascular disease compared with men with concentrations <9 µg/l. When these men were removed from the analysis, there was no longer evidence of a trend for death from cardiovascular disease (P=0.66). There was no evidence of a significant relation between red cell folate concentration and death from all causes, cardiovascular disease, or coronary heart disease. The relative risk was close to unity for the lowest compared with the highest group in both men and women. We also found no significant relation between vitamin concentrations and deaths from cardiovascular or coronary heart disease with survival analysis restricted to 15 years (data not shown).

**Discussion**

We found no evidence of an independent association between folate or vitamin B-12 concentrations and death from cardiovascular or coronary heart disease. The trends in risk factors and mortality in the Busselton population are similar to those in other parts of Australia. In addition, adjusted estimates of relative risk of coronary heart disease and stroke in the Busselton population seem consistent with estimates in other populations of similar age and ethnicity. Vital status could be ascertained for 98% of the cohort after 29 years, and the numbers of observed deaths from cardiovascular and coronary heart disease were sufficiently large for reliable statistical analyses. We excluded participants who died within the first three years of survey to limit the possibility of reverse causality when examining the association between vitamin concentration and mortality.

The 1969 Busselton health survey measured serum and red cell folate and serum vitamin B-12 concentrations as a means of estimating the nutritional status of the population. Folate and B-12 nutrition seemed to be generally sufficient, with only 3.1% of the population having a reduced folate and 0.4% having a reduced B-12 concentration based on the normal reference intervals for red cell folate (115-600 µg/l) and serum B-12 (160-850 ng/l). The measured vitamin levels cannot be equated to values obtained with current assay methods. However, the absolute vitamin concentrations were unimportant as our analysis was based on estimating relative risks.

**Folate**

Previous studies have not measured red cell folate concentrations. Red cell folate indicates tissue folate status and reflects folate turnover over the preceding two to three months. It is a more reliable indicator of long term folate intake than serum folate, which has a high intranidividial variability because it reflects intake only in the preceding few days. This explains why we found only a modest correlation between red cell and serum folate concentrations in our population.

Studies examining the association between serum or dietary folate concentrations and coronary heart disease have produced inconsistent results (table 4). Morrison et al found a significant inverse association between serum folate concentration and 15 year mortality from coronary heart disease, especially in women. However, they found no association between dietary folate consumption and risk of fatal coronary heart disease. Other cohort studies with follow up periods ranging from 3.3 to 20 years have found no significant increase in risk of non-fatal or fatal coronary heart disease for participants in the lowest versus highest group of serum folate concentration (table 4). The high intranidividial variability of serum folate measurements may have diluted any observed association with risk of coronary heart disease in these studies as well as in our study, which found an inverse (but not significant) association between serum folate concentration and fatal cardiovascular disease in women who had no cardiovascular disease at baseline. We do not have replicate measure-

relatively small effect on homocysteine concentration given that vitamin B-12 supplementation has a coronary heart disease. This may not be surprising. We found no association between vitamin B-12 independently associated with coronary heart disease. Factors or unmeasured risk behaviours that are as a high folate intake from food and vitamin showed no independent association of baseline serum folate over time in our population and being usually related to a problem of absorption rather than nutrition. Other cohort studies have not measured serum B-12 concentrations. However, these results need to be interpreted with caution as a high folate intake from food and vitamin supplements may also be related to other dietary factors or unmeasured risk behaviours that are independently associated with coronary heart disease.

Vitamin B-12
We found no association between vitamin B-12 concentration and death from cardiovascular or coronary heart disease. This may not be surprising given that vitamin B-12 supplementation has a relatively small effect on homocysteine concentration and B-12 deficiency is uncommon in the general population for prevention of cardiovascular disease should not be routinely recommended in the general population until the benefit is proved by controlled clinical trials. Moderate hyperhomocysteinaemia is thought to be an independent risk factor for cardiovascular disease. High homocysteine concentrations in the general population are mainly due to insufficient folate and B vitamin concentrations. Evidence linking serum or dietary folate and B vitamin levels to incident cardiovascular disease is inconclusive.

What this study adds
A large community cohort followed for 29 years showed no independent association of baseline serum and red cell folate and serum B-12 concentrations with mortality from cardiovascular disease. Vitamin therapy to lower homocysteine concentrations should not be routinely recommended in the general population until the benefit is proved by controlled clinical trials.
