Reliability of symptoms to determine use of bone scans to identify bone metastases in lung cancer: prospective study

Martin Hetzel, Juergen Hetzel, Coskun Arslanademir, Karin Nüssle, Holger Schirrmeister

Based on the hypotheses that most skeletal metastases in lung cancer are clinically symptomatic, that the incidence of bony metastases in early stages is low, and that bone scintigraphy has a sensitivity of nearly 100%, leading professional societies recommend diagnostic skeletal imaging depending on clinical symptoms. No study has assessed the significance of skeletal symptoms as a criterion for skeletal imaging in patients with lung cancer since 1991. But in the intervening period gamma camera technology has been considerably refined and more sensitive methods such as magnetic resonance imaging have become available for skeletal imaging.

We redetermine the role of symptoms and serum concentrations in detecting bony metastases in lung cancer and reassess the accuracy of bone scans for screening.

Participants, methods, and results

From September 1999 to September 2001 we recruited 153 consecutive patients at University Hospital Ulm. We included patients based on cytological or histological evidence of lung cancer returned no more than 10 days before entry into the study. Of these, 121 (79%; 88 men and 33 women; median age 66, range 40-83 years) agreed to participate. Exclusion criteria were a history of malignant disease, pregnancy, and age less than 18 years. All patients gave written informed consent. Diagnosis was non-small cell lung cancer in 84 patients and small cell lung cancer in 37 patients. We questioned and examined all patients about skeletal complaints. Physical examination included percussion, compression, flexion, extension, and rotation of the vertebral column and extremities and evaluations of patients' neurological status. We also measured serum calcium and alkaline phosphatase concentrations. New skeletal symptoms within the previous six months were judged as suspicious for bony metastases.

We did bone scans blinded to the history and findings of the physical examination. The combined results of magnetic resonance imaging of the vertebral column and patients' subsequent clinical course were the ideal for identification of bony metastases. We found skeletal metastases in 40 patients (33%). Incidence was nearly identical at 33% (28) in patients with non-small cell lung cancer and 32% (12) in those with small cell lung cancer. These patients had normal serum alkaline phosphatase and calcium concentrations. Three quarters (91) of patients had symptoms. In only 10% (25) of patients with symptoms did the location of metastases correspond to the symptoms. Routine bone scans correctly identified skeletal metastases in 29 patients (sensitivity 73%; 95% confidence interval 50% to 85%). Bone scans were correctly negative in 80 of 81 patients (specificity 99%; 93% to 100%). If bone scans were done in only the 91 patients reporting skeletal complaints, the sensitivity would have been reduced to 53%. A further restriction of the method to those 23 patients with suspicious complaints would have resulted in a further reduction in sensitivity to 20% (8 patients).

Comment

Only a small proportion of bone metastases can be recognised based on clinical symptoms or by increased serum alkaline phosphatase or calcium levels. Because of the high incidence of arthritic complaints, guidelines mandating bone scans only in patients with skeletal complaints often result in coincidental discovery of bony metastases (figure). Restricting bone scans to patients whose skeletal complaints were clinically

The prevalence of symptoms of asthma, allergic rhinitis, and atopic eczema in children in the United Kingdom ranks among the highest in the world.1 The evidence from most repeat surveys is that prevalence has increased over the past three decades,2 but the most recent of these studies observed that from 1991 to 1998 the increase was confined to milder symptoms of asthma.3 Since the early 1990s the incidence of asthma episodes presenting to general practitioners, and of hospital admissions, has fallen substantially.2

Participants, methods, and results

In 1995, as part of the international study of asthma and allergies in childhood (ISAAC), we surveyed symptoms of atopic disease in England, Scotland, Wales, and the offshore islands of Guernsey, Isle of Man, and Jersey.1 2 A self completed questionnaire which adhered to the core ISAAC protocol was administered to secondary school children aged 12-14 in school years 8 and 9 (S2 and S3 in Scotland). In 2002 the survey was repeated in Scotland, Wales, and the islands in the same school years, using the same questionnaire and procedures in the same period of the year and, mostly, in the same schools. In England, only the schools in the South East Region were surveyed a second time. The table shows the changes in prevalence over the seven years from 1995 to 2002.

Overall, the prevalence of any wheezing or whistling in the chest in the past 12 months fell from 34% to 28% (16% relative reduction). Even larger proportional falls were observed for frequent attacks (35%) and speech limiting attacks (24%). Large reductions were also observed for symptoms of allergic rhinoconjunctivitis (16%) and atopic eczema (30%). The proportion of children reporting “ever” having had “asthma” or “eczema” increased (26% and 15%), as did the lifetime prevalence of “hay fever” (8%). Trends in the four regions were similar.

The fall in prevalence is consistent with other sources. From 1995 to 2000, hospital admissions for asthma fell by 20.4% in 10-14 year olds in England, Scotland, and Wales combined (see table). From 1995 to 2002, in 10-14 year olds in a sample of 75 English and Welsh practices, visits to a general practitioner for episodes of asthma decreased by 47% (from 38.3 to 20.4 per 1000). Recently released data from the health survey for England shows that from 1997 to 2001, the 12 month prevalence of wheezing in 10-14 year olds, based on parental reporting, fell by 18% (from 17.4% to 14.2%).

Comment

The burden of self reported asthma and other allergic diseases among adolescents has changed substantially for the better in recent years throughout the British Isles. These trends correspond to those seen in the 10-14 year age group in hospital admissions, consultations with general practitioners, and parentally reported symptoms in the health survey for England. Just as we do not know why the prevalence of symptoms of asthma has increased since the 1950s, we do not know why it should now be decreasing. The increased use of effective treatment, especially inhaled steroids, is likely to have been important in reducing the severity of episodes, but this is unlikely to explain the decrease in mild wheeze symptoms, which is more consistent with a fall in the underlying prevalence. The
