Mumps outbreaks across England and Wales in 2004: observational study

Emma Savage, Mary Ramsay, Joanne White, Stuart Beard, Heather Lawson, Rashpal Hunjan, David Brown

Introduction

In October 1988, routine immunisation against mumps was introduced in the United Kingdom as a combined measles, mumps, and rubella (MMR) vaccine for children aged 12-15 months. Although the incidence of mumps declined quickly, mathematical modelling supported the introduction of a second dose of MMR in 1996. In 1999, numbers of cases of mumps in teenagers in England and Wales began to rise. We report a further increase in the incidence of mumps in 2004.

Participants, methods, and results

Notifications of clinically diagnosed and laboratory confirmed mumps cases are collated for England and Wales by the Health Protection Agency Centre for Infections. Confirmed cases include those obtained by routine follow-up of all notified cases where IgM is detected in oral fluid.

In 2004, the number of mumps notifications in England and Wales increased to 16,436 from 4,204 in 2003. A total of 8,104 cases of mumps were confirmed in 2004, compared with a total of 3,907 cases in the previous five years. All regions reported more cases in 2004 than in 2003. Cases were predominantly in older teenagers and young adults born before 1987 (figure), and most were in those born between 1983 and 1986. Many of this group are currently at tertiary level education institutions and are associated with outbreaks in universities across England and Wales. Outbreaks in the same birth cohorts have also been reported in military establishments and prisons. Only 2.4% (197/8,104) of confirmed cases in 2004 occurred in children who would have been offered two doses routinely—those born between 1993 and 1999 (figure); only 29 of these had documented receipt of two doses of MMR. Only 62 cases (0.8%) have been confirmed in children born after 1999.

Comment

During 2004, numbers of notifications and confirmed cases of mumps increased dramatically in all regions across England and Wales, after several years of moderately increased incidence. Most cases are in young adults born before 1988, who would not have been routinely scheduled for MMR during childhood. The highest attack rate was in those born between 1983 and 1986, who were too old to be offered MMR vaccination routinely when it was introduced in 1988, although some may have received one dose of MMR as part of a catch-up programme offered at school entry. These individuals would have missed the opportunity for mumps exposure during childhood because high coverage in younger children had reduced circulation of mumps in the UK. Older individuals are more likely to have had mumps when it was still a common childhood infection. The absence of cases in children in younger cohorts, including those affected by the fall in MMR coverage since 1995, confirms the effectiveness of the current vaccination policy.

The mumps component of the MMR vaccine used in the UK is believed to offer around 90% protection for one dose, although recent reports indicate that this could be as low as 64%. This outbreak confirms that the current, two dose MMR schedule is effective in preventing mumps. In addition to improving routine coverage of MMR, reviewing the vaccination status of all school leavers is recommended, to ensure that they have received two doses of MMR. Other opportunities to offer MMR vaccine to the age group at highest risk, such as when entering university or other institutions, should also be considered.

What is already known about this topic

The incidence of mumps fell after the MMR was introduced in 1988.

The number of confirmed mumps cases in 2004 has risen across England and Wales, with a number of reported outbreaks in universities.

What this study adds

The current mumps outbreak has been predominantly in older teenagers and young adults, who would not have been offered two doses of MMR.

This confirms the effectiveness of the current vaccination policy.

It has been hypothesised that the measles, mumps, and rubella vaccine (MMR vaccine) increases the risk of autism and Crohn's disease. Although a possible link with autism has been extensively studied and refuted,1 a link with Crohn's disease has not. I tested this hypothesis by analysing trends in age specific admission rates for Crohn's disease in children and adolescents to determine if the introduction of MMR vaccine in 1988 increased rates in those populations that were offered the vaccine as infants.

Methods and results

Counts of admissions, taken as the first consultant episode in a hospital stay, in patients aged ≤18 years with a main diagnosis of Crohn's disease in England (population 50 million) were available for the 12 years from April 1991 to March 2003.1 I restricted the analysis to emergency admissions as these were probably less susceptible to changes in thresholds for admission and clinical practice than elective admissions. In the first two years of the MMR vaccination programme, the percentages of children completing a primary course of MMR vaccine in their second year of life were 7% and 68%; thereafter the percentage was at least 84%.≥

Initially, temporal trends in age specific rates were plotted, differentiating between the rates for those born before and after the introduction of the vaccine. (Rates for patients aged 16 to 18 years—too old to have been offered the vaccine as infants—provided information on underlying trends unaffected by MMR vaccination in infancy.) Data for those born in 1987–8, of whom only 68% were vaccinated as infants, were excluded from the analysis. The MMR vaccination programme was then modelled as a variable with two levels (vaccination rate of ≥84% and of ≤7%) using Poisson regression, with adjustment for year of admission and age in single years (as categorical variables).

There were 4463 admissions for Crohn's disease, 923 of which occurred in populations with a vaccination rate of ≥84% (those born in 1988–9 or later). Although the age specific rates increased over the study period, no obvious changes occurred that coincided with the introduction of MMR vaccine (figure). The estimated rate ratio for the MMR vaccination programme (rates in populations with a vaccination rate of ≥84% compared with those with a rate of ≤7%) was 0.95 (95% confidence interval 0.84 to 1.08).

Comment

The introduction of MMR vaccine, replacing the single measles vaccine, was not associated with an increase in Crohn's disease. Given the precision of the rate ratio, all but a small risk would have been detected. This was an ecological study, and findings from such studies generally need to be treated cautiously because of...
