Abstract

Objectives To summarise evidence on the associations of maternal anaemia and prenatal iron use with maternal haematological and adverse pregnancy outcomes; and to evaluate potential exposure-response relations of dose of iron, duration of use, and haemoglobin concentration in prenatal period with pregnancy outcomes.

Design Systematic review and meta-analysis

Data sources Searches of PubMed and Embase for studies published up to May 2012 and references of review articles.

Study selection criteria Randomised trials of prenatal iron use and prospective cohort studies of prenatal anaemia; cross sectional and case-control studies were excluded.

Results 48 randomised trials (17 793 women) and 44 cohort studies (1 851 682 women) were included. Iron use increased maternal mean haemoglobin concentration by 4.59 (95% confidence interval 3.72 to 5.46) g/L compared with controls and significantly reduced the risk of anaemia (relative risk 0.50, 0.42 to 0.59), iron deficiency (0.59, 0.46 to 0.79), iron deficiency anaemia (0.40, 0.26 to 0.60), and low birth weight (0.81, 0.71 to 0.93). The effect of iron on preterm birth was not significant (relative risk 0.84, 0.68 to 1.03). Analysis of cohort studies showed a significantly higher risk of low birth weight (adjusted odds ratio 1.29, 1.09 to 1.53) and preterm birth (1.21, 1.13 to 1.30) with anaemia in the first or second trimester. Exposure-response analysis indicated that for every 10 mg increase in iron dose/day, up to 66 mg/day, the relative risk of maternal anaemia was 0.88 (0.84 to 0.92) (P for linear trend<0.001).

Birth weight increased by 15.1 (6.0 to 24.2) g (P for linear trend=0.005) and risk of low birth weight decreased by 3% (relative risk 0.97, 0.95 to 0.98) for every 10 mg increase in dose/day (P for linear trend<0.001). Duration of use was not significantly associated with the outcomes after adjustment for dose. Furthermore, for each 1 g/L increase in mean haemoglobin, birth weight increased by 14.0 (6.8 to 21.8) g (P for linear trend=0.002); however, mean haemoglobin was not associated with the risk of low birth weight and preterm birth. No evidence of a significant effect on duration of gestation, small for gestational age births, and birth length was noted.

Conclusions Daily prenatal use of iron substantially improved birth weight in a linear dose-response fashion, probably leading to a reduction in risk of low birth weight. An improvement in prenatal mean haemoglobin concentration linearly increased birth weight.

Introduction

Iron deficiency is the most widespread nutritional deficiency in the world.^{1 2} It is the most common cause of anaemia during pregnancy. Other causes include parasitic diseases such as malaria, hookworm infections, and schistosomiasis; micronutrient deficiencies including folic acid, vitamin A, and vitamin B12; and genetically inherited haemoglobinopathies such as thalassaemia.³ According to the Nutrition Impact Model Study's 2011 estimates, the worldwide prevalence of anaemia in pregnant women was 38% (95% confidence interval 33% to 43%), translating into 32 (28 to 36) million pregnant women

globally.⁴ Because of the persistently high burden of disease, the World Health Organization has long recommended the prenatal use of iron supplements in low and middle income countries, and this is also recommended in many high income countries.^{1 5 6}

In 2011 more than 50% of anaemia in pregnant women was due to iron deficiency in regions where fewer other causes were present.⁴ Multiple observational studies on prenatal anaemia and only a few on iron deficiency anaemia are available.^{7 8} One of the main reasons is the use of haemoglobin concentration as a proxy for iron deficiency anaemia due to its low cost and relative ease of determination. Reviews of observational studies show an association between prenatal anaemia and risk of preterm birth, but evidence for other outcomes is inconsistent.⁹⁻¹¹

Clinical trials of prenatal iron supplementation have shown improvement in haemoglobin concentration, but evidence of an effect on birth outcomes has been found to be inconclusive.^{12 13} The Cochrane review on prenatal iron supplementation found no evidence of a reduction in risk of low birth weight and preterm birth,¹² whereas Imdad et al showed a reduction in risk of low birth weight only.¹⁴ Because of the conflicting findings from reviews of observational studies and randomised trials, we have done a comprehensive systematic review evaluating all evidence by collating data from randomised trials and prospective cohort studies in one report. Furthermore, to the best of our knowledge, no systematic evaluation has been done of exposure-response relations of iron dose and haemoglobin concentration in the prenatal period with adverse birth outcomes, identification of which would prove critical to the efforts to reduce this burden.

We did a meta-analysis of randomised trials of the overall effect of use of iron, with or without folic acid, on maternal haematological status, morbidity, and birth outcomes and evaluated the existence and shape, whether linear or non-linear, of the iron dose-response relation with risk of maternal anaemia, birth weight, and risk of low birth weight and preterm birth. Because a greater proportion of women in low and middle income countries seek antenatal care late in pregnancy, we also evaluated the relation of these outcomes with the duration of iron use. As cohort studies often have larger sample sizes and are more likely to have measured baseline haemoglobin, we then summarized evidence from prospective cohort studies by doing a meta-analysis examining the association of prenatal anaemia with birth outcomes. Finally, we assessed exposure-response relations of haemoglobin concentration with birth weight and risk of low birth weight and preterm birth by using data from trials with haemoglobin measurement and cohort studies, and we compared the magnitude of these associations.

Methods

We followed the Cochrane Collaboration's method for this review.¹⁵ We did comprehensive, systematic literature searches of PubMed (from 1966 to 31 May 2012), and Embase (from 1974 to 31 May 2012). We developed separate search strategies consisting of a combination of free text words (tw), words in titles/abstracts (tiab), and medical subject headings (mesh) for exposure, participants, and study design; we then combined these by using "AND" (see box). We placed no language or publication restrictions. We adapted the PubMed search strategy for Embase. We screened reference lists of identified studies and published reviews for additional studies.

Study selection

Two reviewers (BAH and IO) independently screened titles and abstracts. They then critically reviewed full texts of selected studies to assess eligibility. Any discrepancy between the reviewers was resolved through discussion.

We included randomised trials in pregnant women of daily oral iron or iron and folic acid use compared with placebo, no iron, or no iron and folic acid. We included trials of both supplementation and fortification. We excluded trials of multiple vitamins and minerals, except those that examined the additional effect of iron or iron with folic acid in which all treatment groups received similar vitamins and minerals (except for iron or iron and folic acid). We included trials examining maternal haematological, morbidity, and birth outcomes. Maternal haematological outcomes included mean haemoglobin concentration (g/L), anaemia (defined as haemoglobin <110 g/L), iron deficiency (defined as serum ferritin <12 µg/L), and iron deficiency anaemia (defined as haemoglobin <110 g/L and serum ferritin <12 µg/L) in the second or third trimester or at delivery and in the postpartum period. Birth outcomes included mean duration of gestation (weeks), preterm birth (defined as birth of a neonate <37 weeks of gestation), mean birth weight (g), low birth weight (defined as birth weight <2500 g), mean birth length (cm), small for gestational age birth (defined as birth weight below the 10th centile of the gestational age and sex), stillbirth (defined as death of a fetus after 28 weeks of gestation), perinatal mortality (defined as deaths including stillbirths and neonatal deaths before 7 days of life), and neonatal mortality (defined as death of a neonate in the first month of life). Other maternal outcomes included gestational diabetes mellitus, infection during pregnancy and postpartum, maternal malaria and parasitaemia, and placental malaria. We placed no limits on gestational age at the time of starting iron or duration of iron use. We included both individual and cluster randomised trials.

For analysis of observational studies, we included prospective cohort studies that allowed examination of the association of baseline anaemia with the above specified birth outcomes. We included studies defining anaemia as haemoglobin <100 g/L to haemoglobin <115 g/L. When haemoglobin was not reported but haematocrit was available, we estimated haemoglobin concentrations (g/L) by dividing haematocrit by 3 and then multiplying by 10. We excluded cross sectional and case-control studies, as these do not allow assessment of the temporal association between exposure and an outcome. We also excluded trials with a quasi-randomised design owing to the high risk of bias and studies in HIV infected women or those with haemoglobinopathies. We excluded trials evaluating different doses of iron, unless they presented comparison groups that met our eligibility criteria.

Data extraction and synthesis

Two reviewers (BAH and IO) independently extracted data by using a pilot tested data extraction form. We collected information from each study on study design, setting, participants, exposure, time of assessment of exposure, outcomes, confounders, and measures of association. Exposure details for trials included treatment, dose, gestational age at start, and duration and frequency of iron use; for cohort studies, we recorded definition of anaemia and time of assessment. We extracted raw data and effect estimates (relative risks or odds ratios) with 95% confidence intervals. We extracted odds ratios from cohort studies; when available in the original publication, we also extracted odds ratios adjusted for the potential

confounders. For trials with multiple intervention groups or varying doses of iron, we extracted data for eligible comparison groups. For cluster randomised trials, we extracted estimates adjusted for the cluster design. We incorporated data such that each participant was included in an analysis only once to avoid unit of analysis error. We assessed each trial's methodological quality by using four criteria—namely, randomisation technique, concealment of allocation, blinding, and loss to follow-up. We categorised each criterion as adequate, inadequate, or unclear. We labelled a trial as high quality if it was rated as adequate for randomisation and allocation concealment plus either blinding or loss to follow-up under 20%. We assessed the methodological quality of cohort studies by comparing crude and adjusted estimates, controlling for the study confounders. Eligible foreign language papers were translated into English; however, 11 foreign language papers could not be translated and were not included (see table supplement for references^{w1-11}). We actively contacted study authors to seek clarifications and request missing or additional data or reanalysis, if needed. Discrepancies between the reviewers were resolved through discussion, by contacting the authors, or by consultation with a third reviewer (WWF or ME).

Statistical analysis

We used fixed effects (Mantel-Haenszel method^{16 17}) and random effects (DerSimonian and Laird method¹⁸) models to calculate summary estimates for the overall effect of iron, with or without folic acid, followed by separate meta-analyses for the effects of iron alone and iron with folic acid. We present summary effects as relative risks for binary outcomes and as mean differences for continuous outcomes, with their respective 95% confidence intervals. To study the effect of methodological quality of trials, we did sensitivity analyses using data from high quality trials only. We did meta-analyses for outcomes with data for at least five trials or comparison groups.

We assessed presence of between study heterogeneity by using the Q statistic with its P value and I² statistics.^{19 20} The I² statistic is used to quantify the proportion of total variation in the effect estimation that is due to between study variation. If the Q statistic P value was below 0.10 and I² exceeded 50%, we considered heterogeneity to be substantial and presented a random effects model. We explored sources of heterogeneity through subgroup and meta-regression analyses,²¹ using the pre-specified subgroups based on trials' characteristics: country category (low or middle income versus high income),²² malaria endemicity (endemic versus non-endemic), initial mean haemoglobin concentration (anaemic (<110 g/L) versus non-anaemic (≥110 g/L)), and gestational age at start of treatment (early as ≤21 weeks versus late as >22 weeks of gestation). As malaria endemicity was not available for most

included studies, we used the malaria atlas project database to characterise endemicity of the study area within a country,²³ assuming that the endemicity had not changed. Study areas with stable malaria transmission were labelled as endemic, whereas those with unstable transmission or that were risk free were categorised as non-endemic. We further investigated sources of heterogeneity by doing meta-regression analysis and used the residual I² to estimate residual heterogeneity after adjusting for the characteristic of interest. We assessed publication bias by visual inspection of funnel plots for asymmetry and through Begg's rank correlation and Egger's linear regression tests.^{24 25} We did subgroup analysis and assessments of publication bias for outcomes with 10 or more trials or comparison groups.

We examined the iron dose-response relation with risk of maternal anaemia, low birth weight, and preterm birth by using methods proposed by Greenland et al and Orsini et al, which take into account the correlation between log-relative risk estimates across the exposure categories.^{26 27} To evaluate a potential non-linear dose-response relation, we fitted fixed effects restricted cubic spline regression models using four knots at the fifth, 35th, 65th, and 95th centiles of the exposure data and assessed significance of spline variables through hypothesis testing.²⁸ For the iron dose-response relation with birth weight, we used a mixed effects meta-regression model to estimate the mean change in birth weight per unit change in iron dose.²⁹ We evaluated non-linearity by using the regression model described above. We also assessed the association with duration of iron use in the above models by adding study specific durations. We assessed the exposure-response relations of mean haemoglobin concentration in the third trimester or at delivery with birth weight and risk of low birth weight and preterm birth by using these statistical methods. We did sensitivity analysis, subgroup analysis, and assessments of publication bias and exposure-response relation only for the overall analysis of iron use, with or without folic acid.

For the meta-analysis of cohort studies, we used odds ratios or mean differences to calculate summary measures. We did a separate meta-analysis for cohort studies to study the association of baseline haemoglobin with the outcomes and to assess whether the findings from cohorts and trials were consistent. We did sensitivity analysis by analysing study specific crude odds ratios and adjusted odds ratios separately and comparing the summary estimates to establish the effect of adjustment for confounders. We assessed presence of between study heterogeneity by using the methods described above. We used the following pre-specified study characteristics for subgroup analysis: period of gestation of anaemia assessment (first and second trimester (<27 weeks of gestation) versus third trimester (≥27 weeks)), country category, and malaria endemicity. We used funnel plots and Harbord's test to assess publication bias.³⁰

We did not use Egger's test owing to the statistical problem of standard error of log odds ratio being mathematically linked to the size of log odds ratio, even in the absence of small study effects. For the exposure-response analysis of haemoglobin concentration on birth weight, low birth weight, and preterm birth, mean haemoglobin concentrations for the anaemic and non-anaemic groups were not available for all cohort studies. To evaluate this relation, we selected a country from each high, middle, and low income countries category and used their mean haemoglobin concentrations for studies with missing values. We selected studies in Hong Kong, China, and HIV negative women in Tanzania for high income, middle income, and low income categories. We used the statistical methods described above to evaluate the exposure-response relations.

We used Stata (version 10.1), SAS (version 9.2), and RevMan (version 5.1) for the analyses. Statistical significance was defined at the 0.05 level.

Results

Literature search

Figure 1 shows results from the literature search and study selection process. We identified a total of 13 668 potentially eligible citations, of which 5882 were from PubMed and 7786 from Embase. Screening of 10 821 titles and abstracts after removing duplicates identified 1048 citations for full text review. An additional 12 references were identified from reference lists of previously published reviews. Detailed review of identified full text papers yielded 152 reports of 120 eligible studies, including 62 randomised trials and 58 cohort studies. Of 120 studies, we further excluded 28 studies as data were either missing or presented in a format that precluded inclusion (see table supplement for references¹²⁻³⁹).

Study characteristics

Supplementary tables 1 and 2 show the characteristics of included trials and cohort studies. Briefly, 17 793 pregnant women were included in 48 randomised trials, of which 27 were conducted in high income countries (4861 women)³¹⁻⁵⁷ and 21 in low or middle income countries (12 932 women).⁵⁸⁻⁷⁸ Thirty four trials compared the effect of daily iron use with no iron or placebo, four trials compared iron with folic acid versus folic acid alone, 14 trials included a comparison of iron with folic acid versus placebo or no treatment, and 10 compared iron with a micronutrient or several micronutrients versus the same set of micronutrients except iron. Two trials evaluated the effect of iron fortification compared with no fortification.^{47 61} Eighteen trials had adequate randomisation, allocation concealment, and blinding or loss to follow-up under 20% (supplementary table 1).^{31 32 36 38 41 42 45 47 52-54 58 63 66 70 71 73 79} Only two trials randomised villages or sectors (clusters).^{58 74} The dose of iron in included trials ranged from 10 mg to 240 mg daily; one trial used a daily dose of 900 mg.³⁷ Duration of supplementation varied from seven to eight weeks up to 30 weeks during pregnancy. One trial also randomised participants to malaria prophylaxis and another randomised them to anti-helminthic drugs, along with the intervention and control treatment.^{63 70}

We included 44 cohort studies including 1 851 682 women. Of these, 22 studies were from high income countries (650 126 women)⁸⁰⁻¹⁰¹ and 22 were from low or middle income countries (1 201 556 women).¹⁰²⁻¹²³ Anaemia was defined differently in included studies, with definitions ranging from haemoglobin <100 g/L to haemoglobin <115 g/L. Studies assessed anaemia at varying times during pregnancy (17 measured haemoglobin values in the first or second trimester and nine in the third

trimester). Five studies measured concentrations in all three trimesters of pregnancy, in which case we included first trimester values in the analysis. Eight studies used values measured at the first antenatal visit, whereas in 10 studies the time of assessment of anaemia was not specified (supplementary table 2).

Evidence from randomised trials

We firstly present findings for the overall effect of iron, with or without folic acid, followed by the effect of iron only and iron with folic acid.

Findings for overall effect of iron, with or without folic acid, on haematological outcomes

Table 1 summarizes the overall effect of iron on haematological outcomes. We included 36 trials measuring haemoglobin concentration in the third trimester or at delivery and showed a significantly higher mean haemoglobin concentration in the iron, with or without folic acid, group (mean difference 4.59 g/L, 95% confidence interval 3.72 to 5.46; 36 trials; fig 2). We found no heterogeneity associated with this analysis ($I^2=0\%$; $P>0.05$). The funnel plot did not suggest evidence of publication bias (fig 3), whereas Egger and Begg tests were significant (both $P<0.05$). We found the effect of iron on the postpartum haemoglobin concentration to be significant, whereas that on the second trimester haemoglobin concentration was non-significant (supplementary figures 1 and 2). The effect of intervention on maternal anaemia was assessed in 21 trials. Use of iron, with or without folic acid, led to 50% reduction in risk of anaemia in the third trimester or at delivery (relative risk 0.50, 0.42 to 0.59; 19 trials; table 1, supplementary figure 3). Heterogeneity was significant, and results should be interpreted with caution ($P<0.001$; $I^2=83\%$). A visual inspection of the forest plot indicated that heterogeneity could be due to variation in the degree of difference in effect rather than the direction. The funnel plot and Begg and Egger tests (both $P<0.05$) suggested publication bias (supplementary figure 4). Effects on the second trimester or postpartum concentrations could not be evaluated owing to the small number of trials (less than five).

Because haemoglobin concentration is an important indicator of maternal health, we did subgroup analysis to study the effects in various pre-specified subgroups. Mean haemoglobin concentration in the third trimester or at delivery was significantly higher in the low or middle income country category than in the high income category (test $P=0.003$) and for initial mean haemoglobin concentrations <110 g/L versus ≥ 110 g/L (test $P=0.005$) (table 2). We identified no significant difference for malaria endemicity and time of start of iron use in subgroups (both test $P>0.05$). Meta-regression analyses for maternal anaemia showed that the effects were significantly larger in the high income country category (test $P=0.009$), with initial mean haemoglobin concentration ≥ 110 g/L (test $P=0.008$), and in malaria non-endemic regions (test $P=0.003$). Adjusting for these covariates independently in meta-regression did not explain heterogeneity substantially (table 3).

Use of iron, with or without folic acid, also provided significant improvements in iron indicators in the third trimester or at delivery; analysis showed significant reductions in the risk of iron deficiency (relative risk 0.59, 0.44 to 0.79; $I^2=79\%$; eight trials) and iron deficiency anaemia (0.40, 0.26 to 0.60; $I^2=33\%$; six trials) (table 1; supplementary figures 5 and 6). Sources of heterogeneity for iron deficiency could not be evaluated owing to the small number of available trials.

Findings for overall effect of iron, with or without folic acid, on birth outcomes

Analysis showed a significantly higher mean birth weight in the iron group compared with the control group (mean difference 41.2 (1.2 to 81.2) g; $I^2=99\%$; 19 trials; table 1, supplementary figure 7). Analysis of the high quality trials alone also indicated a significant effect (mean difference 68.7 (37.7 to 99.7) g; $I^2=97\%$; 12 trials). Heterogeneity was high, but subgroup analysis and meta-regression showed that birth weights were not significantly different in subgroups (test $P>0.05$). Iron use led to a reduction of 19% in risk of low birth weight (relative risk 0.81, 0.71 to 0.93; $I^2=1\%$; 13 trials; table 1, fig 4). The analysis of the high quality trials alone found similar results (table 1). The funnel plot and Begg and Egger tests for low birth weight and for birth weight suggested no evidence of publication bias (all $P>0.05$); however, the funnel plot for birth weight indicated some asymmetry.

Use of iron did not have a significant effect on preterm birth, duration of gestation, small for gestational age births, and birth length ($P>0.05$) (table 1; supplementary figures 8-11). Sensitivity analyses found similar effects among the high quality trials. The funnel plot and Egger and Begg tests (both $P>0.05$) for preterm birth did not suggest the presence of publication bias. A small number of trials reported effects on stillbirths ($n=3$), perinatal mortality ($n=4$), neonatal mortality ($n=3$), and maternal morbidity outcomes such as gestational diabetes ($n=1$), infection during pregnancy ($n=2$), puerperal sepsis ($n=2$), and malaria indicators ($n=2$), precluding further analyses for these outcomes.

Exposure-response relation of iron dose with haematological and birth outcomes

We noted a significant non-linear, inverse relation between dose of iron and risk of maternal anaemia in the third trimester or at delivery (non-linear test $P<0.001$; 18 trials; table 4; supplementary figure 12). The relation did not change when we excluded the trial that used 900 mg of iron daily³⁷ (non-linear test $P<0.001$; 17 trials; table 4). Because the iron dose recommended is either 60 mg or lower,^{124 125} we restricted analysis to trials providing up to 66 mg iron/day to see if giving 60 mg daily has any benefit over lower doses. For a 10 mg increase in iron dose per day, the relative risk of anaemia was 0.88 (0.84 to 0.92; P for linear trend <0.001 ; 11 trials; table 4; supplementary figure 13). We used duration data from trials to evaluate the association of duration of use with anaemia; duration of use, adjusted for dose of iron, was not associated with anaemia ($P>0.05$).

Analysis of the exposure-response relation between iron dose and birth weight found an increase of 15.1 (6.0 to 24.2) g in birth weight for every 10 mg increase in daily iron dose ($P=0.005$; 18 trials; table 4). Similarly, risk of low birth weight decreased by 3% for every 10 mg increase in daily iron dose (relative risk 0.97, 0.95 to 0.98; P for linear trend <0.001 ; 13 trials; table 4). We found no evidence of a non-linear association with either birth weight or low birth weight (both $P>0.05$). When we restricted analyses to trials using up to 66 mg/day iron, findings for low birth weight did not change (table 4; supplementary figure 14); however, we found evidence of non-linearity for birth weight ($P<0.001$; 14 trials; supplementary figure 15). Duration of iron use was not significantly associated with either outcome, after adjustment for dose. Iron dose was not associated with risk of preterm birth (relative risk 0.99, 0.95 to 1.04; P for linear trend = 0.67; 12 trials; table 4).

Exposure-response relation of haemoglobin concentration with birth outcomes

A unit increase in mean haemoglobin concentration in the third trimester or at delivery linearly increased birth weight by 14.0 (6.8 to 21.8) g ($P=0.002$; 16 trials; table 5). We found no evidence of a non-linear association ($P>0.05$; supplementary figure 16). However, the effect on risk of low birth weight was non-significant (relative risk 0.96, 0.84 to 1.09; P for linear trend = 0.21; 11 trials; table 5, supplementary figure 17). Similarly, the effect on risk of preterm birth was also non-significant (relative risk 0.99, 0.94 to 1.04; P for linear trend = 0.70; eight trials; table 5, supplementary figure 18).

Findings for effect of iron only versus no iron/placebo on haematological and birth outcomes

Use of iron was associated with significantly increased mean haemoglobin concentration in the third trimester or at delivery (mean difference 4.50 (3.62 to 5.39) g/L; $I^2=0\%$; 31 trials; supplementary figure 19) and in the postpartum period (7.01 (0.36 to 13.66) g/L; $I^2=0\%$; eight trials; supplementary figure 20) compared with no iron or placebo. Similar to the overall analysis, we found significant reductions in the risk of anaemia (relative risk 0.56, 0.48 to 0.65; $I^2=75\%$; 17 trials), iron deficiency (0.59, 0.44 to 0.79; $I^2=79\%$; eight trials), and iron deficiency anaemia (0.37, 0.23 to 0.60; $I^2=47\%$; five trials) (supplementary figures 21-23). Heterogeneity was significant, and findings should be interpreted with caution. However, visual inspection of the forest plots indicated that heterogeneity seemed to be due to the variation in effects sizes, rather than the direction of the effect. Use of iron was associated with a significant increase in birth weight (mean difference 40.8 (0.97 to 80.6) g; $I^2=99\%$; 16 trials) and reduction in risk of low birth weight (relative risk 0.81, 0.71 to 0.91; $I^2=9\%$; 10 trials). Effects on duration of gestation (mean difference 0.11 (-0.35 to 0.57) weeks; nine trials), preterm birth (relative risk 0.92, 0.80 to 1.07; 10 trials), small for gestational age births (relative risk 0.84, 0.66 to 1.07; six trials), and birth length (mean difference -0.93 (-4.76 to 2.90) cm; seven trials) were not significant (supplementary figures 24-29).

Findings for effect of iron with folic acid versus no iron and folic acid/placebo on haematological and birth outcomes

Iron with folic acid was associated with a significant increase in mean haemoglobin concentration (mean difference 10.41 (5.36 to 15.46) g/L; $I^2=0\%$; nine trials) and reduction in risk of anaemia in the third trimester or at delivery (relative risk 0.44, 0.37 to 0.53; $I^2=44\%$; five trials) (supplementary figures 30 and 31). Effects on other haematological and pregnancy outcomes could not be evaluated owing to the small number of available trials (less than five).

Evidence from cohort studies

Association between anaemia and birth outcomes

Table 6 summarises the association between prenatal anaemia, irrespective of the time of assessment, and birth outcomes. Prenatal anaemia significantly increased the risk of low birth weight compared with no anaemia (crude odds ratio 1.25, 1.08 to 1.45; $I^2=90\%$; 25 studies); however, the association was non-significant when we pooled adjusted estimates extracted from the included studies (adjusted odds ratio 1.13, 0.94 to 1.35; $I^2=86\%$; nine studies) (supplementary figures 32 and 33). We noted a significantly higher risk of preterm birth in the anaemic

group (crude odds ratio 1.28, 1.12 to 1.47; $I^2=89\%$; 26 studies). This association remained significant when we pooled adjusted estimates (adjusted odds ratio 1.28, 1.11 to 1.48; $I^2=83\%$; 13 studies) (supplementary figures 34 and 35). We found a significantly higher risk of stillbirth in the anaemic group (crude odds ratio 1.19, 1.09 to 1.29; $I^2=24\%$; 12 studies; supplementary figure 36); however, adjusted estimates could not be pooled because only two studies presented them. Anaemia was marginally associated with the duration of gestation ($P=0.05$) but not with birth weight; associations with small for gestational age births and perinatal mortality were not significant ($P>0.05$) (supplementary figures 37-41). Associations with birth length and neonatal mortality could not be evaluated owing to paucity of data.

We found significant heterogeneity in the preterm birth and low birth weight analyses. Subgroup analysis found a significantly higher risk of preterm birth with first or second trimester anaemia (adjusted odds ratio 1.21, 1.13 to 1.30; $I^2=0\%$; seven studies) but not with third trimester anaemia (adjusted odds ratio 1.20, 0.80 to 1.79; $I^2=90\%$; six studies) (test $P=0.71$) (supplementary table 3). We found no significant difference for subgroups of country category (high (adjusted odds ratio 1.26, 1.02 to 1.57; $I^2=87\%$; nine studies) versus low or middle income countries (adjusted odds ratio 1.30, 1.05 to 1.61; $I^2=77\%$; five studies) (test $P=0.83$) (supplementary table 3). We could not do subgroup analysis for malaria endemicity owing to the small number of studies in one of the subgroups. Supplementary table 4 presents findings for the low birth weight subgroup analysis, which showed significantly higher risk with first or second trimester anaemia (adjusted odds ratio 1.29, 1.09 to 1.53; $I^2=82\%$; six studies) and no significant associations in subgroups of high income countries (adjusted odds ratio 1.21, 0.95 to 1.53; $I^2=90\%$; six studies) or malaria non-endemic countries (adjusted odds ratio 1.13, 0.94 to 1.35; $I^2=86\%$; nine studies); however, we could not calculate P values for subgroup differences owing to the small number of studies in one of the subgroups. Funnel plots and Harbord tests for low birth weight and preterm birth (both $P>0.05$) did not suggest any evidence of publication bias.

Exposure-response relation of haemoglobin concentration with birth outcomes

Analysis of the cohort studies showed non-significance of the exposure-response relation between mean haemoglobin concentration and birth weight (mean difference 3.2 (−17.9 to 24.3) g; $P=0.77$; nine studies; supplementary table 5). More studies assessed the association with low birth weight, and the association was significant although the magnitude was small (relative risk 0.99, 0.98 to 0.99; P for linear trend <0.001 ; 25 studies; supplementary table 5). We also found the exposure-response relation of mean haemoglobin concentration in the first or second trimester with risk of preterm birth to be significant (relative risk 0.98, 0.98 to 0.99; P for linear trend <0.001 ; 12 studies; supplementary table 5).

Discussion

In meta-analyses of randomised trials of prenatal iron use, we found evidence of significant reductions in maternal anaemia, iron deficiency, iron deficiency anaemia, and risk of low birth weight. Dose-response analysis showed a linear decrease in maternal anaemia with higher doses of iron, up to 66 mg/day. Higher doses of iron were associated with a linear increase in birth weight and decrease in risk of low birth weight. With iron up to 66 mg/day, we found a non-linear association with birth weight but a linear reduction in risk of low birth weight.

Furthermore, higher mean haemoglobin concentration in the prenatal period linearly increased birth weight with a dose-response relation. We did not find any evidence of reduction in risk of preterm birth as a result of iron use; however, meta-analysis of cohort studies indicated a higher risk of preterm birth with first or second trimester anaemia and with lower mean haemoglobin concentration.

Strengths of meta-analysis in relation to other meta-analyses

This meta-analysis is a comprehensive evaluation of the evidence, incorporating randomised trials and cohort studies, with examination of associations with haematological, morbidity, and birth outcomes in one report. To the best of our knowledge, this is the first meta-analysis to examine the exposure-response relation of dose of iron, duration of use, and haemoglobin concentration on birth weight and risk of low birth weight and preterm birth. We made various comparisons evaluating the overall effect of iron, iron only, and iron with folic acid. We made an effort to extract all available data from trials, especially those with multiple comparison groups. In addition, we evaluated effects in various predefined subgroups and did meta-regression to evaluate sources of heterogeneity. We also did sensitivity analysis to assess the effect of the methodological quality of trials on effect estimates.

Results in relation to other meta-analyses

Our findings of significant improvement in maternal haematological outcomes as a result of iron use corroborate those of previous reviews.^{12 14 126 127} We noted a greater effect on haemoglobin concentration in low or middle income countries and with lower initial mean haemoglobin concentration (<110 g/L). We showed a positive, linear dose-response relation between iron dose up to 66 mg daily and risk of maternal anaemia, indicating a benefit of giving higher rather than lower doses over this range. These findings are biologically plausible, as several mechanisms regulating intestinal iron absorption have been identified.^{77 128 129} Human studies and animal models have shown that depleted body iron stores enhance absorptive capacity in the duodenum, which is increased several-fold in the presence of iron deficiency. Another important regulator is bone marrow erythropoiesis, which adjusts intestinal absorption in response to the erythropoietic demands. Review of epidemiological studies shows that women in low or middle income countries generally enter pregnancy with more limited iron stores and lower haemoglobin concentrations than do those in high income countries. An increasing demand for iron in these women may thus enhance intestinal absorption to a greater extent, resulting in a greater haematological response. Improved haematological status during pregnancy may also reduce the mortality risk in women with antepartum or postpartum haemorrhage and lead to improved iron status in the postpartum period.^{9 11}

We found a significant reduction in the risk of low birth weight as a result of iron use, which is similar to the finding of Imdad et al.¹³⁰ This, however, is in contrast to that of the Cochrane review,¹² which did not find evidence of a decreased risk. We present below a brief description of the methodological differences between the various meta-analyses. The Cochrane review included 45 randomised and quasi-randomised trials identified up to March 2009 and found no significant effect on birth weight, low birth weight, preterm birth, and small for gestational age births.¹² We, in this meta-analysis, included larger number of randomised trials with searches updated to 31 May 2012. We excluded quasi-randomised trials, as these have

a high risk of bias owing to the inadequate method of random sequence generation or allocation concealment. The differences in the eligibility criteria for selecting studies between the two reviews and the dates of literature search led to a different set of trials being analysed in the two reviews. Imdad et al evaluated a smaller set of outcomes and identified 30 randomised and quasi-randomised trials up to June 2011.¹³⁰ The analyses were associated with significant heterogeneity, but the sources of heterogeneity were not examined using study characteristics. Yakoob et al and Sloan et al included randomised and quasi-randomised trials evaluating effects on haematological outcomes only.^{126 127} None of the earlier reviews did meta-regression to evaluate sources of heterogeneity or an assessment of exposure-response relations, which were objectives of our meta-analysis.

The dose-response analysis showed a linear increase in birth weight with higher iron doses. More importantly, higher mean haemoglobin concentration linearly increased birth weight. These results indicate that for every 10 g/L increase in mean haemoglobin concentration in the third trimester or at delivery, the birth weight would increase by 143 (95% confidence interval 68 to 218) g. The dose of iron recommended by WHO is 60 mg/day, whereas the Institute of Medicine has set the tolerable upper intake level as 45 mg/day owing to the gastrointestinal side effects with higher doses.^{124 125} Trials comparing various doses of iron have been done and indicate a larger improvement in iron status with higher doses, but no difference in anaemia and other clinical outcomes was noted.^{131 132} We also showed a reduction in risk of low birth weight with higher iron doses and identified a similar relation with iron dose up to 66 mg/day. An increase in birth weight of the magnitude specified above could prove critical for the survival of neonates born with birth weights in the lower range.¹³³ Recent literature also provides insight into the biological mechanisms that could potentially explain the effects on birth weight. A potential role of the placenta in the regulation of iron transfer and the transport proteins involved has been identified.^{78 134 135} Animal models also indicate a role of fetal liver iron stores in regulating iron absorption through the placenta.^{135 136} In contrast to the significant effect on birth weight from trials, this meta-analysis of cohort studies did not indicate a significant increase in birth weight with increasing haemoglobin concentration. Several reasons for this observation are possible. Firstly, as the data used in this analysis were observational in nature, confounding of the association could have occurred. Secondly, as the mean haemoglobin concentrations for most studies were missing, we assumed that countries within the same category would have similar mean haemoglobin concentrations. Under that assumption, we used similar values for all countries in low, middle, or high income categories, which may not have been completely accurate.

Our analysis of cohort studies showed a significantly increased risk of preterm birth with first or second trimester anaemia. These results are in agreement with previous reviews of observational studies.^{10 11} Xiong et al included 10 observational studies published up to 1999 in their review.¹⁰ Both cohort and case-control studies were included in this review. The Global Burden of Disease Comparative Risk Assessment analysis of iron deficiency anaemia included 10 studies examining association with perinatal mortality outcome.⁹ This review included cross sectional studies examining the association of haemoglobin measured at delivery with pregnancy outcomes, together with other observational designs. Cross sectional and case-control studies do not allow evaluation of the temporal association between the exposure and outcome, and they have high risk of bias. These were, therefore, excluded from our

meta-analysis. We also did sensitivity and subgroup analyses and explored exposure-response relations between haemoglobin concentration and birth outcomes, which were not included in earlier reviews of observational studies. Although we found a significant risk of preterm birth in our meta-analysis of cohort studies, the meta-analysis of trials indicated a non-significant effect of iron use on preterm birth risk. It is plausible that causes of anaemia other than iron deficiency are implicated in the pathway; a few have been identified.¹²⁰ Existence of chronic hypoxia may induce a stress response, resulting in production of corticotrophin releasing hormone, elevated concentrations of which have been identified as a major risk factor of preterm birth. Additionally, the risk of preterm birth may increase owing to oxidative damage to erythrocytes and the fetoplacental unit. Lastly, it may increase the risk of infections, stimulating production of corticotrophin releasing hormone and increasing the risk of preterm birth.

A potential concern exists regarding an increased risk of adverse maternal and birth outcomes associated with high haemoglobin concentrations. Several studies have found increased risks of low birth weight, preterm birth, and small for gestational age birth with high maternal haemoglobin concentrations.^{94 97 119 137} The adverse birth outcomes may be comparable to those of anaemia, but the causes may be different.^{121 137} This, however, warrants further investigation and was not a part of our review. The interaction between iron supplementation and susceptibility to infections, including malaria, also remains a concern. Studies of iron supplementation of children in malaria endemic countries suggest that iron supplementation increases the risk of morbidity and mortality among children^{138 139}; however, studies of antenatal iron use have shown conflicting results for malaria outcomes.^{68 140 141} We could not evaluate these outcomes in this review owing to the paucity of data.

Limitations of meta-analysis

Our review has several limitations. Firstly, we could not evaluate associations with several outcomes owing to the paucity of data. These include stillbirths and neonatal and perinatal mortality in iron use meta-analyses and birth length and neonatal mortality in the cohort studies analysis. Secondly, significant heterogeneity existed for several outcomes that could not be explained substantially by our pre-specified subgroups. This limits our understanding of the association in various settings and restricts the generalisability of our findings. Thirdly, a small number of trials had evaluated the effect of iron fortification in pregnant women, so a separate meta-analysis for fortification trials could not be done. Fourthly, although we used adjusted estimates from cohort studies, these results still could have been biased owing to residual confounding, in either direction, depending on the nature of the residual confounding. Finally, as explained earlier, for the exposure-response analysis of cohort studies, we assumed mean haemoglobin concentrations for studies with missing values, which may have introduced bias towards the null due to random measurement error.

Conclusions: implications for practice and future research

Our findings suggest that use of iron in women during pregnancy may be used as a preventive strategy to improve maternal haematological status and birth weight. Prenatal anaemia and iron deficiency have been identified as one of the preventable risk factors for disease with a substantial disease burden.¹⁴² This calls for a rigorous evaluation of the effectiveness of existing antenatal care programmes in high burden countries to identify gaps in policy and programme implementation. Targeted

interventions to strengthen the infrastructure of antenatal care should be used. Future research to explore feasible strategies of iron delivery in a country setting and evaluation of the effectiveness of other strategies, such as fortification and dietary diversification, should be done.

We thank Paul Bain at the Countway Library of Medicine, Harvard Medical School, for assistance in the development of search strategy; Ruifeng Li at the Department of Epidemiology, Harvard School of Public Health, for statistical assistance; and Xin Li for research assistance.

Writing Team: Batool A Haider (BAH), Ibrionke Olofin (IO), Molin Wang (MW), Donna Spiegelman (DS), and Wafaie W Fawzi (WWF) (Harvard School of Public Health, Boston, MA, USA); Majid Ezzati (ME) (School of Public Health, Imperial College London, London, UK).

Iron Review and Re-analysis Team: Batool A Haider and Ibrionke Olofin (Harvard School of Public Health, Boston, MA, USA); Gustavo F Gonzales (GFG) and Vilma Tapia (VT) (Universidad Peruana Cayetano Heredia, Lima, Peru); Aiguo Ren (AR) and Juan Wang (JW) (Peking University Health Science Center, Beijing, China).

Contributors: WWF, ME, and BAH designed the review. BAH wrote and implemented the protocol under the guidance of ME and WWF. BAH developed the search strategy and ran searches. BAH and IO screened the studies and extracted data. BAH analysed the data. DS and MW provided statistical guidance. BAH wrote the first draft of the manuscript. BAH, WWF, ME, and DS contributed to the interpretation of results and subsequent revisions. All writing team members approved the final version of the manuscript. GFG, VT, AR, and JW reanalysed their cohort study data for inclusion in the review. WWF is the guarantor.

What is already known on this topic

Synthesis of evidence from observational studies indicates an association between prenatal anaemia and risk of preterm birth, but evidence on other birth outcomes is inconsistent

Evidence from randomised trials on the effect of prenatal iron use on adverse birth outcomes is also inconclusive

What this study adds

This comprehensive meta-analysis of randomised trials suggests that prenatal iron use is associated with a significant increase in birth weight and reduction in risk of low birth weight

A dose-response relation of higher iron dose with increasing birth weight and decreasing risk of low birth weight exists

An exposure-response relation also exists between increasing mean haemoglobin concentration in the prenatal period and higher birth weight

Tables

Table 1 | Summary of effects of iron use on haematological and pregnancy outcomes

Haematological outcomes (in third trimester or at delivery)	All trials					High quality trials				
	No of trials	WMD or RR (95% CI)	Significance of effect (P value)	Test for heterogeneity (P value)	I ² (%)	No of trials	WMD or RR (95% CI)	Significance of effect (P value)	Test for heterogeneity (P value)	I ² (%)
Haemoglobin (g/L)	36	4.59 (3.72 to 5.46)	<0.001	0.98	0	15	4.20 (3.17 to 5.22)	<0.001	0.95	0
Anaemia	19	0.50 (0.42 to 0.59)	<0.001	<0.001	83	8	0.66 (0.57 to 0.76)	<0.001	<0.001	72
Iron deficiency	8	0.59 (0.44 to 0.79)	<0.001	<0.001	79	5	0.70 (0.55 to 0.91)	<0.001	0.001	79
Iron deficiency anaemia	6	0.40 (0.26 to 0.60)	<0.001	0.18	33	4	—	—	—	—
Pregnancy outcomes										
Birth weight (g)	19	41.21 (1.20 to 81.23)	<0.001	<0.001	99	12	68.67 (37.67 to 99.68)	<0.001	<0.001	97
Low birth weight	13	0.81 (0.71 to 0.93)	0.001	0.44	1	7	0.82 (0.72 to 0.94)	0.003	0.15	37
Gestational age (weeks)	10	0.11 (-0.35 to 0.57)	0.64	1.00	0	6	0.12 (-0.36 to 0.60)	0.63	1.00	0
Preterm birth	12	0.84 (0.68 to 1.03)	0.09	0.68	0	9	0.84 (0.68 to 1.05)	0.12	0.67	0
Small for gestational age birth	8	0.85 (0.67 to 1.08)	0.17	0.02	59	6	0.84 (0.62 to 1.14)	0.26	0.005	70
Birth length (cm)	8	-1.08 (-4.97 to 2.80)	0.58	0.76	0	6	-1.15 (-5.15 to 2.84)	0.58	0.41	0

RR=relative risk; WMD=weighted mean difference.

Table 2 | Subgroup analysis for effect of iron use on haemoglobin concentration in third trimester or at delivery (g/L)

Characteristic	No of trials	Mean difference (95% CI)	Significance of effect (P value)	Test for interaction (P value)
Country:				0.003
Low or middle income	14	8.34 (5.69 to 11.00)	<0.001	
High income	22	4.13 (3.21 to 5.06)	<0.001	
Malaria endemicity:				0.087
Endemic	7	8.16 (3.98 to 12.34)	<0.001	
Non-endemic	29	4.43 (3.53 to 5.32)	<0.001	
Baseline anaemia:				0.005
Anaemic	7	10.17 (6.14 to 14.19)	<0.001	
Non-anaemic	26	4.29 (3.39 to 5.19)	<0.001	
Start of iron use:				0.086
Early (≤21 weeks' gestation)	32	4.48 (3.60 to 5.36)	<0.001	
Late (>22 weeks' gestation)	4	9.73 (3.80 to 15.66)	<0.001	

Table 3| Subgroup analysis and meta-regression for effect of iron use on maternal anaemia in third trimester or at delivery

Characteristic	No of trials	Relative risk (95% CI)	Univariate meta-regression		
			P value for test for heterogeneity by covariate	Residual I ² after adjustment for covariate (%)	Reduction in I ² after adjustment for covariate (%)
Country:			0.009	82	1
Low or middle income	8	0.58 (0.50 to 0.67)			
High income	11	0.23 (0.12 to 0.45)			
Malaria endemicity:			0.003	79	5
Endemic	6	0.61 (0.53 to 0.71)			
Non-endemic	13	0.30 (0.19 to 0.46)			
Baseline anaemia:			0.008	74	10
Anaemic	5	0.60 (0.51 to 0.71)			
Non-anaemic	12	0.32 (0.21 to 0.50)			
Start of iron use:			0.60	84	0
Early (≤21 weeks of gestation)	13	0.50 (0.39 to 0.65)			
Late (>22 weeks of gestation)	6	0.45 (0.33 to 0.61)			

Table 4 | Summary of exposure-response relations with haematological and birth outcomes (trials)

Exposure: increase in iron dose (10 mg/day)	No of trials	WMD or RR (95% CI)	P value
Maternal anaemia			
All trials	18	0.99 (0.990 to 0.995)	<0.001
All trials (excluding trial with iron dose 900 mg/day)	17	0.93 (0.91 to 0.94)	<0.001
Trials with iron dose up to 66 mg/day	11	0.88 (0.84 to 0.92)	<0.001
Low birth weight			
All trials	13	0.97 (0.95 to 0.98)	<0.001
Trials with iron dose up to 66 mg/day	11	0.96 (0.95 to 0.98)	<0.001
Birth weight			
All trials	18	15.10 (6.00 to 24.20)	0.005
Trials with iron dose up to 66 mg/day	14	16.70 (7.29 to 26.11)	0.004
Preterm birth			
All trials	12	0.99 (0.95 to 1.04)	0.67
Trials with iron dose up to 66 mg/day	11	0.99 (0.95 to 1.03)	0.50

RR=relative risk; WMD=weighted mean difference.

Table 5 | Summary of exposure-response relations of haemoglobin difference* (1 g/L) in prenatal period with birth outcomes (trials)

Outcomes	No of trials	WMD or RR (95% CI)	P value
Low birth weight	11	0.96 (0.84 to 1.09)	0.21
Birth weight	16	14.00 (6.80 to 21.80)	0.002
Preterm birth	8	0.99 (0.94 to 1.04)	0.70

RR=relative risk; WMD=weighted mean difference.

*Difference in mean haemoglobin concentration between intervention and control groups in included studies.

Table 6 | Summary estimates of anaemia, irrespective of time of anaemia assessment, on pregnancy outcomes (cohort studies)

Outcome	Unadjusted estimates					Adjusted estimates				
	No of studies	Crude OR or MD* (95% CI)	Significance of effect (P value)	Test for heterogeneity (P value)	I ² (%)	No of studies	Adjusted OR or MD (95% CI)	Significance of effect (P value)	Test for heterogeneity (P value)	I ² (%)
Birth weight	9	-20.15 (-60.91 to 20.61)	0.33	<0.001	70	0	—	—	—	—
Low birth weight	25	1.25 (1.08 to 1.45)	0.003	<0.001	90	9	1.13 (0.95 to 1.35)	<0.001	<0.001	86
Gestational age	6	-0.37 (-0.74 to -0.00)	0.05	<0.001	81	0	—	—	—	—
Preterm birth	26	1.28 (1.12 to 1.47)	<0.001	<0.001	89	13	1.28 (1.11 to 1.48)	0.001	<0.001	83
Small for gestational age	13	1.04 (0.80 to 1.35)	0.77	<0.001	92	9	1.08 (0.90 to 1.29)	0.43	<0.001	88
Stillbirth	12	1.19 (1.09 to 1.29)	<0.001	0.21	24	2	—	—	—	—
Perinatal mortality	8	1.03 (0.77 to 1.37)	0.86	0.003	67	2	—	—	—	—

MD=mean difference; OR=odds ratio.
