Transcatheter versus surgical aortic valve replacement in patients with severe aortic stenosis at low and intermediate risk: systematic review and meta-analysis

Reed A Siemieniuk,1,2 Thomas Agoritsas,1,3 Veena Manja,1,4,5 Tahira Devji,1 Yaping Chang,1 Malgorzata M Bala,6 Lehana Thabane,1 Gordon H Guyatt1

ABSTRACT
OBJECTIVE
To examine the effect of transcatheter aortic valve implantation (TAVI) versus surgical replacement of an aortic valve (SAVR) in patients with severe aortic stenosis at low and intermediate risk of perioperative death.

DESIGN
Systematic review and meta-analysis.

DATA SOURCES
Medline, Embase, and Cochrane CENTRAL.

STUDY SELECTION
Randomized trials of TAVI compared with SAVR in patients with a mean perioperative risk of death <8%.

REVIEW METHODS
Two reviewers independently extracted data and assessed risk of bias for outcomes important to patients that were selected a priori by a parallel guideline committee, including patient advisors. We used the GRADE system was used to quantify absolute effects and quality of evidence.

RESULTS
4 trials with 3179 patients and a median follow-up of two years were included. Compared with SAVR, transfemoral TAVI was associated with reduced mortality (risk difference per 1000 patients: −30, 95% confidence interval −49 to −8, moderate certainty), stroke (−20, −37 to 1, moderate certainty), life threatening bleeding (−252, −293 to −190, high certainty), atrial fibrillation (−178, −150 to −203, moderate certainty), and acute kidney injury (−53, −39 to −62, high certainty) but increased short term aortic valve reintervention (7, 1 to 21, moderate certainty), permanent pacemaker insertion (134, 16 to 382, moderate certainty), and moderate or severe symptoms of heart failure (18, 5 to 34, moderate certainty). Compared with SAVR, transapical TAVI was associated higher mortality (57, −16 to 153, moderate certainty, P=0.015 for interaction between transfemoral versus transapical TAVI) and stroke (45, −2 to 125, moderate certainty, interaction P=0.012). No study reported long term follow-up, which is particularly important for structural valve deterioration.

CONCLUSIONS
Many patients, particularly those who have a shorter life expectancy or place a lower value on the risk of long term valve degeneration, are likely to perceive net benefit with transfemoral TAVI versus SAVR. SAVR, however, performs better than transapical TAVI, which is of interest to patients who are not candidates for transfemoral TAVI.

SYSTEMATIC REVIEW REGISTRATION
PROSPERO CRD42016042879.

Introduction
Severe symptomatic aortic stenosis is common and, without aortic valve replacement, results in a life expectancy of less than three years.1 Each year in the United States, about 75,000 patients undergo surgical aortic valve replacements (SAVR).2 Because aortic stenosis increases with age, this number will increase with the evolving population demographic.3 Transcatheter aortic valve implantation (TAVI) is an increasingly popular alternative to SAVR, at least in part because it does not require thoracotomy.4 Current practice guidelines recommend either TAVI or SAVR in patients at high surgical risk, defined as a Society of Thoracic Surgeons predicted risk of mortality (STS-PROM) score of 8% or less, but recommend SAVR over TAVI for lower risk patients.56 Despite this recommendation, half of the TAVI centers in Europe perform TAVI because it does not require thoracotomy.4 The authors claimed non-inferiority for TAVI versus SAVR for the primary composite endpoint of death from any cause or disabling stroke at two years. Two recent meta-analyses that included patients from PARTNER 2A suggested that compared with SAVR, TAVI was associated with reduced odds of major bleeding, acute kidney injury, and new onset atrial fibrillation and with increased risks of pacemaker implantation, vascular complications, and aortic regurgitation.78 The reviews did not, however, address the durability of valves and need for...
aortic reintervention after TAVI. Moreover, the reviews failed to formally rate either the quality of the evidence or the credibility of subgroup analyses (leaving the credibility of findings uncertain) or provide absolute risks, crucial for trading off the desirable and undesirable aspects of TAVI versus SAVR.

The limitations of the prior review prompted us to perform an updated systematic review and meta-analysis of randomized controlled trials of TAVI compared with SAVR for patients at low and intermediate surgical risk. We conducted this systematic review to inform recommendations for the first in a new series in The BMJ of trustworthy recommendations published in response to potentially practice changing evidence, so called Rapid Recommendations. Our review complements a co-published meta-analysis of observational data on baseline risk to inform absolute effects and a systematic review on patients’ values and preferences to inform the relative importance of outcomes (box 1).

Methods
Protocol
The registered study protocol is available on PROSPERO (CRD42016042879).

Information sources
A search from a previous systematic review that we judged as comprehensive included articles up to 15 July 2012. We complemented that review with a search of Medline, Medline in-process, Embase, and Cochrane CENTRAL from 1 January 2012 to 12 May 2016 using a combination of keywords and MeSH terms for “aortic stenosis” AND “valve replacement”, using the sensitive search filters for therapeutic interventions developed by the Health Information Research Unit at McMaster University (appendix 1). There were no restrictions on language or publication type. We also searched all references from included studies and studies citing the included studies on Google Scholar.

Study selection
We included randomized controlled trials comparing TAVI and SAVR in patients with severe aortic stenosis and a mean risk score of 8% or less. All titles and abstracts were screened in duplicate with the Evidence online service (Alfred Health, Melbourne, Australia). If either reviewer judged that the study could meet the inclusion criteria, we assessed eligibility in duplicate using the full text.

Data collection process
Two reviewers independently abstracted data and resolved conflicts by discussion. When possible, we analyzed patients in groups to which they were randomized and from the as treated population when intention to treat data were not available.

Summary measures and patient involvement
The outcomes chosen in this research paper were influenced by two people with experience of living with aortic stenosis. It was part of a wider project and is published in the Rapid Recommendation series exploring TAVI versus SAVR for people with severe aortic stenosis. Two patients worked with the panel to list the outcomes that were important to them; they identified several outcomes that other panel members had identified and also uniquely highlighted pain and recovery time as critical to decision making. We were not able to find direct evidence for those outcomes in the randomized controlled trials. All outcomes are consistent with the Valve Academic Research Consortium (VARC)-2 standardized endpoint definitions.

Risk of bias and quality of evidence
We assessed risk of bias in duplicate with a modified Cochrane tool; reviewers resolved conflicts through consensus. With respect to missing data, we judged individual trials at high risk of bias if data from more than 10% of patients were unavailable.

We rated the certainty in the evidence informing absolute effects using the GRADE approach. All authors, in consultation with the parallel Rapid Recommendations guidelines panel, participated in and came to consensus regarding certainty of estimates ratings. The GRADE risk of bias assessment included plausible worst case sensitivity analyses addressing missing follow-up data.

Synthesis of results
For dichotomous outcomes we conducted a random effects meta-analysis using both Hartung-Knapp-Sidik-Jonkman (HKSJ) 95% confidence intervals and DerSimonian and Laird confidence intervals of relative risks and chose between the two for the primary report based on plausibility of results. We intended to pool continuous outcomes with mean differences with a similar statistical approach. We present the DerSimonian and Laird confidence intervals for all dichotomous and continuous outcomes with mean differences with a similar statistical approach. We present the DerSimonian and Laird confidence intervals for all dichotomous and continuous outcomes with mean differences with a similar statistical approach. We present the DerSimonian and Laird confidence intervals for all dichotomous and continuous outcomes with mean differences with a similar statistical approach. We present the DerSimonian and Laird confidence intervals for all dichotomous and continuous outcomes with mean differences with a similar statistical approach. We present the DerSimonian and Laird confidence intervals for all dichotomous and continuous outcomes with mean differences with a similar statistical approach. We present the DerSimonian and Laird confidence intervals for all dichotomous and continuous outcomes with mean differences with a similar statistical approach.
the longest follow-up. We then pooled the odds ratios with random effects, weighted by inverse variance. We assumed and tested the proportional odds across NYHA classes for each individual study, using likelihood ratio tests. In this analysis, odds ratios can be interpreted as the odds of having a 1 point increase in NYHA class.

When available, we digitized Kaplan-Meier curves and extracted patient level data on time to event;25 we took this approach for mortality. We checked the proportional hazards assumption and then fitted a Cox regression model with the study as a random effects (shared frailty) variable and report hazard ratios with confidence intervals. Sensitivity analyses were performed with random effects pooling of the hazard ratios reported in individual studies and by pooling dichotomous data at the prespecified timepoints of one month and one year.

We explored effect modification for four variables: transfemoral versus transapical approach, balloon expandable versus self expanding valve, higher perioperative risk (mean risk score ≥6%) versus lower (<6%), and high versus low risk of bias for each trial of bias criterion. We expected that trials would have outcomes more favorable to TAVI than SAVR if they used a transfemoral approach, balloon expandable valves, and enrolled patients with higher perioperative risk. Subgroup analyses were performed only if there were at least two randomized controlled trials in each subgroup or a trial's report permitted a comparison within the trial (for example, the trial reported results separately for patients with lower versus higher risk). We compared the summary estimates from each subgroup with binary, continuous, or ordinal data with a fixed effect comparison between subgroups, except when a within study subgroup was reported. In those situations, we performed two level mixed effects regression with random effects at the study level. For subgroup analyses of time to event data with extracted patient level and within trial subgroup data available, we used a shared frailty Cox model with random effects at the study level. All primary analyses were performed with STATA v13 (StataCorp, College Station, TX).

To calculate absolute effect estimates, we applied the relative effects from this review to the best estimates of baseline risk. Baseline risk estimates were derived from a systematic review of observational studies of SAVR conducted in parallel with this review for mortality and length of hospital stay.33 We used the baseline risk from the SAVR arms of the randomized controlled trials for the other outcomes.

Results
We screened 2734 unique citations, of which 55 were judged potentially eligible during screening of titles and abstracts and four were deemed eligible on full text review (fig 1). The four randomized controlled trials, all published after 2012, included 3179 patients: two trials took place in North America26 and two in Europe.27 28 We included additional data published in five secondary reports.29 30 Most patients were men (54%) and most were aged over 80 (table 1; appendix 2 provides additional study characteristics). One study included patients with a mean risk score of 7.4% but required patients with scores <8% to have additional comorbidities not included in the STS-PROM calculator.26

Two studies used a percutaneous retrograde approach (transfemoral),26 28 one study used a transapical approach,27 and one study used both but stratified randomization based on the heart team’s preferred approach (direct aortic approach was grouped with the transapical approach).8 Across all studies, 94.6% (n=1222) of the patients who underwent percutaneous retrograde TAVI had transfemoral access and 5.6% (n=72) had trans-subclavian access; 77.9% (n=209) of the patients who underwent non-percutaneous TAVI had transapical access and 29% (n=62) had the direct aortic approach.

Assessment of risk of bias
All four trials were at low risk of bias for allocation concealment; none blinded patients, healthcare practitioners, or data collectors, and only one attempted to blind outcome assessors8 (appendix 3). One study blinded data analysts; this study, however, had a greater degree of missing data than other studies.26 The TAVI valve industry funded three studies.8 26 28 All outcomes favoring TAVI, or transfemoral TAVI, over SAVR were robust to worst plausible sensitivity analyses.

Table 2 summarizes findings for all outcomes. Age stratified interactive summary of findings tables are available online at https://www.magicapp.org/public/guideline/AEeKpL. Appendix 4 reports abstracted outcome data by study arm.

Outcomes favoring transfemoral but not transapical TAVI over SAVR
Mortality
At the longest follow-up (median two years), 319 of the 1578 (20.2%) patients undergoing TAVI and 340 of 1550
(21.9%) patients randomized to SAVR died (hazard ratio 0.86, 95% confidence interval 0.74 to 1.01; I²=37.6%). The one month mortality was 3.9% for TAVI and 4.0% for SAVR, despite an average predicted risk score of 5.9%.

There was a significant interaction between transfemoral TAVI and transapical TAVI (P=0.015; appendix 5). Mortality was lower with transfemoral TAVI than with SAVR (hazard ratio 0.79, 95% confidence interval 0.66 to 0.94; I²=0%, 30 fewer per 1000 patients, moderate certainty; fig 2 and table 2). For transapical TAVI, the point estimate suggested harm relative to SAVR, but the confidence interval overlapped no effect (1.34, 0.91 to 1.97; P=0%, 57 more per 1000 patients, moderate certainty; fig 3 and table 2).

**Stroke**

The hazard for stroke was lower with TAVI but the confidence interval overlapped no effect (hazard ratio 0.81, 95% confidence interval 0.63 to 1.01). There was an interaction by approach favoring percutaneous retrograde TAVI over transapical TAVI (P=0.012; fig 4, appendix 5).

The relative risk of stroke compared with SAVR was 0.80 (0.63 to 1.01; I²=0%, 20 fewer per 1000 patients, moderate certainty; table 2) for transfemoral TAVI and 1.67 (0.97 to 2.87; I²=0%, 45 more per 1000 patients, moderate certainty; table 2) for transapical TAVI.

**Acute kidney injury**

Acute kidney injury was less common with TAVI (relative risk 0.48, 95% confidence interval 0.27 to 0.84; I²=50%). Heterogeneity was explained by the TAVI approach (interaction P<0.001; fig 5 and appendix 5).

The risk of acute kidney injury for transfemoral TAVI compared with SAVR was 0.38 (0.27 to 0.52; I²=38%, 178 fewer per 1000 patients, high certainty (table 2 and fig B in appendix 6).

**Outcomes favoring TAVI**

**Bleeding**

The risk of life threatening or disabling bleeding was reduced with TAVI (relative risk 0.39, 95% confidence interval 0.35 to 0.45; I²=31%). Bleeding was reduced with both transfemoral TAVI (0.39, 0.29 to 0.54; I²=71%, 252 fewer per 1000 patients, high certainty; table 2) and transapical TAVI (0.53, 0.42 to 0.67; I²=0%, 194 fewer per 1000 patients, high certainty; table 2), but significantly more so with transfemoral TAVI (P=0.037 for interaction) (fig 6 and appendix 5).

**Atrial fibrillation**

New onset atrial fibrillation (which includes transient periprocedural atrial fibrillation) was less common in patients randomized to TAVI (three studies, relative risk 0.43, 95% confidence interval 0.35 to 0.52; I²=38%, 178 fewer per 1000 patients, high certainty (table 2 and fig B in appendix 6).

**Recovery time**

Three trials reported length of index admission to hospital: patients in the TAVI group in the two larger

§Calculated from baseline risk of death with SAVR in linked meta-analysis of observational studies.
studies (n=2308) were in hospital for about three and four fewer days than the SAVR group (both about 33% shorter and P=0.001). We could not pool data because one randomized controlled trial did not report standard deviations. There was no significant difference in the smallest STACCATO trial, but numbers were not reported.

**Pain**

No studies reported on pain after the intervention.

**Outcomes favoring SAVR**

**Symptoms of heart failure**

The TAVI group had higher odds of having 1 point worse symptoms of heart failure on the NYHA scale than the SAVR group (odds ratio 1.29, 95% confidence interval 1.08 to 1.55 (ordinal regression); P=0%; fig C in appendix 6). For every 1000 patients, 59 (17 to 103) more patients experienced any symptoms of heart failure, of which 18 (5 to 34) were NYHA class III or IV (moderate certainty; table 2). The proportional odds assumption was not violated for any study.

**Aortic valve reintervention**

Aortic valve reinterventions occurred more often in the TAVI group at a median of two years (relative risk 3.25, 95% confidence interval 1.17 to 8.14; P=88%, 7 more per 1000 patients, moderate certainty; table 2 and fig D in appendix 6).

**Insertion of permanent pacemaker**

Permanent pacemaker insertion was more common with TAVI than SAVR (relative risk 2.45, 95% confidence interval 1.29 to 8.14; P=88%, 134 more per 1000 patients, moderate certainty; table 2 and fig 7).

**Moderate or severe aortic valve regurgitation**

Aortic valve regurgitation of at least moderate severity was more common in the TAVI group than in the SAVR group (three randomized controlled trials, relative risk 12.22, 95% confidence interval 5.17 to 28.88; P=0%, 80 more per 1000 patients, high certainty; fig E in appendix 6).

**Fig 4** Forest plot for relative risk of stroke at longest follow-up for transcatheter aortic valve implantation (TAVI) compared with surgical aortic valve replacement (SAVR) for severe aortic stenosis, by valve approach. P=0.012 for interaction.
Outcomes similar between groups

Myocardial infarction
There was no detectable difference in myocardial infarction between TAVI and SAVR (relative risk 0.87, 95% confidence interval 0.58 to 1.29; I²=0%, 5 fewer per 1000 patients, moderate certainty; table 2 and fig F in appendix 6).

Health related quality of life (HRQoL)
Only the US Pivotal and STACCATO trials reported HRQoL. The PARTNER 2A study protocol included HRQoL, but the primary publication did not include these data.8 The US Pivotal trial found an improvement between groups that was important to patients in overall HRQoL at one month in the TAVI group, but there was no difference with SAVR at six months and up to two years.9,30 The STACCATO trial found no differences between groups in HRQoL at three months.37

Sensitivity and other subgroup analyses
The STACCATO trial was stopped early and was the only study to exclusively use a transapical approach.27
Sensitivity analyses without STACCATO did not changestatistical or clinical interpretation for any outcome.

As the included studies otherwise had similar risks ofbias, subgroup analyses by risk of bias were not possi-
ble. Results at one year were similar to those at longest
follow-up (appendix 7). There were no credible sub-
group differences between balloon expandable and self
expanding valves or between trials enrolling patients at
higher or lower perioperative risk (appendix 5).

Discussion
This review shows that in patients with severe aortic
stenosis, for several outcomes, transfemoral TAVI
results in better outcomes relative to SAVR than the
transapical approach relative to SAVR; this was true for
mortality, stroke, acute kidney injury, and bleeding.
These subgroup effects are highly credible. They are
among a small number of a priori hypotheses with a
prespecified direction, including a comparison within
studies, chance is an unlikely explanation, and the
effect is consistent across these related outcomes.

Mortality was reduced with transfemoral TAVI com-
pared with SAVR by about 3%, stroke by 2%, acute kid-
ey injury by 5%, bleeding by 24%, new onset atrial
fibrillation by 18%, and duration of index admission by
days. These benefits, however, come with associ-
ated harms. TAVI was associated with an increased risk
of experiencing symptoms of heart failure by about 6%
(2% of which were moderate or severe), permanent
pacemaker insertion by about 15%, and aortic valve
reintervention over the short term by about 1%.

The picture is quite different with transapical TAVI,
which, though it probably shares benefits of less bleed-
ing, less atrial fibrillation, and shorter hospital stay,
increased the risk of stroke compared with SAVR by
about 5% and could also increase mortality.

Strength and limitations
Strengths of this review include a comprehensive
search for evidence; duplicate assessment of eligibility,
risk of bias, and data abstraction; and assessments of
risk of bias that included addressing loss to follow-up
across studies (and found results robust to loss to fol-
low-up). The review included rigorous assessment of
the quality of evidence (and found the quality for many
important, are more likely to choose SAVR over TAVI or
further increasing the attractiveness of the TAVI
option.

The most important limitation is that the relatively
short duration of follow-up leaves uncertainty about
one critical outcome: the need for reintervention over
the longer term, a major concern with TAVI valves. We
did find that TAVI is associated with a higher risk of aor-
tic valve reintervention, although we were not able to
determine whether this was because of paravalvular
regurgitation or structural valve degeneration, and the
absolute risk was low. The younger the patient, the
greater the extent to which the uncertainty regarding
the long term durability of TAVI valves is likely to influ-
ence the decision between TAVI and SAVR.

Our findings are consistent with those from recently
published meta-analyses for many outcomes, but we
have also provided absolute as well as relative risks and
a formal rating of the quality of the evidence and docu-
mented the credibility of the crucial outcome differ-
ences between transfemoral and transapical TAVI
approaches. Further, we quantified several new find-
ings, including an increased risk of aortic valve reinter-
vention, an increased risk of symptoms of heart failure
with TAVI, and an increased risk of life threatening or
disabling bleeding (rather than major bleeding, which
is less important to patients) with SAVR.

In conclusion, we have clarified the trade-offs
between TAVI and SAVR and identified issues of resid-
ual uncertainty. For patients with lower life expectancy
(such as those aged over 85), in whom longer term valve
deterioration is likely to be less of an issue, the benefits
of transfemoral TAVI versus SAVR on mortality, stroke,
life threatening or disabling bleeding, and a less inva-
sive procedure are compelling. Younger patients (such
as those aged 65-85), who are less concerned about the
limited evidence regarding valve deterioration and the
necessity for a second procedure, might (or might not)
also find these mortality and morbidity benefits com-
pelling. Even younger patients (such as those aged
under 65), for whom valve longevity could be extremely
important, are more likely to choose SAVR over TAVI or
even to choose a mechanical over a bioprosthetic valve.
Finally, patients in whom a transfemoral TAVI approach

https://www.bmj.com/
is not feasible are unlikely to view the transapical approach, which is associated with a higher rate of stroke and a possibly higher mortality rate than SAVR, as an attractive option.

We thank members of the Rapid Recommendations panel for critical feedback on outcome selection. GRADE, judgments, and manuscript feedback, including Per Vandvik, Frederick Spencer, Rodrigo Bagur, Lyubov Lytvyn, Richard Whitlock, Trond Vandtad, David Brigger, Bert Aertgeerts, Susanna Price, Farid Foroutan, Michael Shapiro, and Ray Mertz.

Contributors. Frederick Spencer, Per Vandvik, TSA, RH, and AG provided the conceiving idea. RSA performed the literature search and data analysis. TSA, TM, VM, and AGH interpreted the data analysis. RSA and VM wrote the first draft of the manuscript. TSA, VM, TD, YC, and MMB acquired the data and judged risk of bias in the studies. TD extracted patient level survival data from Kaplan-Meier curves. LT provided statistical advice. TA, VM, TD, YC, MMB, and AGH critically revised the manuscript. RSA had full access to all of the data in the study, and takes responsibility for the integrity of the data and the accuracy of the data analysis. RSA is guarantor.

Funding. This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors. RSA is supported by a Vanier Canada Graduate Scholarship.

Competing interests. All authors have completed the ICMJE uniform disclosure form at www.icmje.org/coi_disclosure.pdf and declare: no support from any organization for the submitted work; no financial relationships with any organizations that might have an interest in the submitted work in the previous three years; no other relationships or activities that could appear to have influenced the submitted work. Ethical approval: Not required.

Transparency declaration. The lead author (RAS) affirms that the manuscript is an honest, accurate, and transparent account of the study being reported; that no important aspects of the study have been omitted; and that any discrepancies from the study as planned have been explained.
