Abstract

Abstract

Objective — To determine the attributable risk of community acquired pneumonia on incidence of heart failure throughout the age range of affected patients and severity of the infection.

Design — Cohort study.

Setting — Six hospitals and seven emergency departments in Edmonton, Alberta, Canada, 2000-02.

Participants — 4988 adults with community acquired pneumonia and no history of heart failure were prospectively recruited and matched on age, sex, and setting of treatment (inpatient or outpatient) with up to five adults without pneumonia (controls) or prevalent heart failure (n=23 060).

Main outcome measures — Risk of hospital admission for incident heart failure or a combined endpoint of heart failure or death up to 2012, evaluated using multivariable Cox proportional hazards analyses.

Results — The average age of participants was 55 years, 2649 (53.1%) were men, and 63.4% were managed as outpatients. Over a median of 9.9 years (interquartile range 5.9-10.6), 11.9% (n=592) of patients with pneumonia had incident heart failure compared with 7.4% (n=1712) of controls (adjusted hazard ratio 1.61, 95% confidence interval 1.44 to 1.81). Patients with pneumonia aged 65 or less had the lowest absolute increase (but greatest relative risk) of heart failure compared with controls (4.8% v 2.2%; adjusted hazard ratio 1.98, 95% confidence interval 1.5 to 2.53), whereas patients with pneumonia aged more than 65 years had the highest absolute increase (but lowest relative risk) of heart failure (24.8% v 18.9%; adjusted hazard ratio 1.55, 1.36 to 1.77). Results were consistent in the short term (90 days) and intermediate term (one year) and whether patients were treated in hospital or as outpatients.

Conclusion — Our results show that community acquired pneumonia substantially increases the risk of heart failure across the age and severity range of cases. This should be considered when formulating

post-discharge care plans and preventive strategies, and assessing downstream episodes of dyspnoea.

Introduction

Community acquired pneumonia is a common condition associated with substantial morbidity and mortality, irrespective of age.¹ Community acquired pneumonia remains the seventh leading cause of death in the United States and accounts for an estimated \$9bn (£7bn; €8bn) in direct healthcare costs and 600 000 admissions to hospital each year.²⁻⁴ Although community acquired pneumonia is often considered an acute event, the long term associated risks are substantial (>50% mortality over five years and a nearly twofold higher risk of subsequent pneumonia than in controls without pneumonia).¹ Moreover, despite major advances in risk stratification and management, downstream sequelae in survivors of pneumonia have not substantively improved over the past decade.⁵

Attention is increasingly focused on the link between pneumonia and subsequent cardiovascular diseases. Several studies have reported a clinically significant short term risk of major cardiovascular disease after acute respiratory tract infections, although the longer term impact of pneumonia on cardiovascular disease is less certain.^{6,7} Heart failure is one cardiovascular complication that seems to be highly prevalent in patients with community acquired pneumonia.⁸⁻²⁸ The mechanism by which pneumonia may influence heart failure is multidimensional. Acute infections can result in reduced myocardial function (eg, septic shock), increased oxygen consumption, tachycardia, and circulatory problems, which may all lead to increased cardiac workload and risk of heart failure.²⁹⁻³¹

Overall, studies have reported incident or worsening heart failure rates of 1.4% in outpatient populations with community acquired pneumonia to as high as 24% among inpatients with

pneumonia.⁷⁻²⁸ Key study limitations have been the inability to distinguish between new onset heart failure and worsening heart failure,⁶⁻²⁸ highly selected samples (cohorts derived from trial participants, patients admitted to hospital from a single medical centre, or elderly patients only),⁶⁻²⁸ potential misclassification of patients with community acquired pneumonia (diagnosis based solely on administrative discharge coding),²¹⁻²⁵ small sample sizes (<500 participants),⁸⁻²⁸ short follow-up periods (eg, 30 day, or in-hospital events only),⁶⁻²⁸ and relatively small number of events.⁸⁻²⁸ Moreover, most studies have only focused on patients admitted to hospital⁸⁻²⁸ and only one study has been able to distinguish the true attributable risk associated with pneumonia on heart failure events compared with a control population without pneumonia or prevalent heart failure; however, this study is limited as controls were not required to be selected from the same site of care (ie, risk estimates for patients with pneumonia admitted to hospital were calculated relative to patients without pneumonia who might not have been admitted) and this study was unable to account for any heart failure events occurring within 30 days of admission for pneumonia.²⁵

Thus it remains unclear if community acquired pneumonia truly increases the risk of incident heart failure in patients relative to those without pneumonia in the short term or longer term and whether the risk extends throughout the range of age and severity of community acquired pneumonia. We therefore assembled a representative population based cohort of patients with pneumonia and age-sex matched population controls without pneumonia, to better understand the clinical course of an episode of pneumonia and its comparative impact on short term and long term incidence of heart failure.

Methods

Patients with pneumonia

This prospective population based clinical registry has been extensively described in previous publications.¹ All patients aged more than 17 years with community acquired pneumonia admitted during 2000-02 to any of the six hospitals or seven emergency departments in Edmonton, Alberta, Canada, which serves a population of approximately one million people, were enrolled in a clinical registry. We excluded patients who had tuberculosis or cystic fibrosis, were immunocompromised (eg, required >10 mg/day prednisone equivalents), or were pregnant. All patients with pneumonia had to have radiographic confirmation by treating clinicians and have at least two signs or symptoms (cough, pleuritic chest pain, shortness of breath, temperature >38°C, and crackles or bronchial breath sounds). All patients were treated according to a validated clinical pathway for community acquired pneumonia, which outlined preferred processes of care.³² Trained research nurses collected data prospectively from presentation to discharge using standardised abstract forms. These data included demographic information, doctor confirmed clinical and laboratory data, and use of prescription drugs within the week before admission.

Matched controls

We frequency matched each patient with pneumonia with up to five controls for age (five year age bands) and sex. Controls were required to be alive at the time of the pneumonia event (cases), presenting at the same site of care (same hospital for inpatients or same emergency department for outpatients) as the patient with pneumonia within the same month and year for a non-pneumonia related diagnosis, and have no history of community acquired pneumonia in the previous year based on

ICD-9-CM (international classification of diseases, nine revision, clinical modification) codes 480-487 or ICD-10 (international classification of diseases, 10th revision) codes J10-J18.

Outcomes

The primary outcome of interest was incident heart failure, which we defined as any heart failure related admission to hospital after the initial pneumonia event (or matched control index event) through to 31 March 2012. Hospital admissions with any diagnostic code for heart failure (ie, primary or any secondary diagnostic codes) were identified using the ICD-9-CM 428.x and ICD-10-CM I50 codes and ascertained by linking patients to comprehensive provincial healthcare administrative databases and vital statistics file.^{33 34} The quality and validity of the databases are routinely checked both provincially and federally with processes to resolve data issues where identified. Secondly, we evaluated the risk of incident heart failure in the short term (within 90 days of discharge after the index event) and intermediate term (within one year of discharge after the index event). We also evaluated a composite endpoint of incident heart failure or all cause mortality over the follow-up period.

Statistical analysis

As we were most interested in new onset heart failure after discharge, we excluded all patients with prevalent heart failure defined as any ICD-9-CM or ICD-10-CM codes for heart failure occurring before or during their initial pneumonia or matched control visit (minimum of three years before). Furthermore, we restricted our cohort to only those patients and controls who survived their initial index hospital admission or emergency department visit. We used Kaplan-Meier curves to describe the time to heart failure related hospital admission from the index pneumonia event (or matched control event).

To evaluate the outcomes for patients with pneumonia compared with controls we used multivariable Cox proportional hazard regression to account for the matched nature of these data. These data are presented as hazard ratios and 95% confidence intervals. No violations of proportional hazards assumptions were found through log-log plots and Schoenfeld residuals. Censoring occurred at departure from Alberta Health or 31 March 2012, providing a maximum follow-up of about 11 years. We did not consider repeat events; only time to first event was evaluated.

To ensure differences in outcomes were not driven by differences in comorbidity, we adjusted all analyses using the 31 coexisting conditions as defined by the Elixhauser comorbidity index. We calculated the Elixhauser index conditions based on diagnostic codes within the three years before the index event for patients with pneumonia and matched controls. Adjustments were also made for socioeconomic status (based on government level of support provided) and Aboriginal status (ie, First Nations and Inuit peoples), as well as the number of physician visits in the one year before the index event as an additional marker of disease burden. We also included age in the models to control for any residual confounding not accounted for in the matching process. In addition, to ensure results were consistent among inpatients and outpatients we stratified all analyses by site of care (inpatient and outpatient) for initial visit. Finally, as there are currently no estimates of heart failure risk in younger adults with community acquired pneumonia, we undertook additional analyses whereby we stratified our analyses into those aged less than 65 years and those aged more than 65 years to better understand the risk of heart failure associated with pneumonia throughout the age range. All analyses were conducted using SAS V9.4 (SAS Institute).

Sensitivity analysis

Firstly, as the primary analysis excluded patients with new onset heart failure during their initial visit for the index event, we expanded the endpoint to include heart failure events that occurred within the initial visit for patients with pneumonia or matched control. Thus, the endpoint considered any patient with a diagnosis of incident heart failure during the index pneumonia event or any subsequent heart failure related hospital admission as having incident heart failure. Secondly, to better evaluate the risk of heart failure over the intermediate to long term, we excluded all patients admitted to hospital for heart failure within the first year after discharge, and repeated our analyses. Thirdly, we expanded our outcome definition to include not only heart failure related hospital admissions after discharge but also heart failure related emergency department visits. For this analysis, we only considered time to first emergency department visit or hospital admission for heart failure. Fourthly, to ensure incident heart failure is specific to pneumonia and not a marker of advanced illness or frailty, we repeated our analyses evaluating the risk of pneumonia on hospital admissions for stroke or fractures. We chose these conditions as they represent other major cardiovascular disease and difficult-to-measure frailty, respectively. Fifthly, as advanced diagnostic tests for heart failure were not routinely available at the time the cohort was established (eg, B type natriuretic peptide), we further excluded all users of diuretics as a prototypical marker of established heart failure to ensure prevalent heart failure could not be affecting our results.³⁵ Sixthly, given the relatively high rates of mortality in this older population, we re-ran our primary analyses using a competing risk framework.³⁶ Finally, we specifically evaluated the risk of new onset heart failure in patients with and without *Streptococcus pneumoniae* bacteraemia.¹⁶

Patient involvement

No patients were involved in setting the research question or the outcome measures, nor were they involved in developing plans for recruitment, design, or implementation of the study. No patients were asked to advise on interpretation or writing up of results. There are no plans to disseminate the results of the research to study participants or the relevant patient community.

Results

Of the 6874 patients with community acquired pneumonia in the cohort, 314 (4.6%) died in hospital, 857 (12.7%) had prevalent heart failure, and 309 (4.5%) had a heart failure code occurring within their initial pneumonia related visit and were excluded from our primary analyses. Of the remaining 5394 patients, 4988 were successfully matched with at least one control (n=23 060; 3676 (73.7%) with five controls). Of the 406 unmatched patients with pneumonia, 22 (0.4%) could not be linked to administrative databases and 384 (7.1%) did not have suitable controls (see supplementary figure). Overall, these patients were similar on age (P=0.17), were slightly more likely to be men (59.1% v 53.1%, P=0.02), and had similar severity of pneumonia (P>0.05). The median follow-up was 9.9 years (interquartile range 5.9-10.6), with a maximum follow-up of 11.4 years. Patients with pneumonia were aged 55 (SD 20) years, with 1762 (35.3%) aged more than 65 years, and most were treated on an outpatient basis (63.4%). Although patients with pneumonia and controls were evenly distributed by sex (P=0.60), controls were slightly younger (53 v 55 years, P<0.001) and had fewer comorbidities (U).

The primary endpoint of incident heart failure occurred in 592 (11.9%) patients with pneumonia compared with 1712 (7.4%) controls (P<0.001), translating into heart failure rates of 1.7 per 100 person years compared with 0.9 per 100 person years, respectively (P<0.001) (U). After adjustment, patients with pneumonia had a higher rate of incident heart failure compared with the controls (adjusted hazard ratio 1.61, 95% confidence interval 1.44 to 1.81, P<0.001, U). Moreover, compared with controls, patients with pneumonia were also more likely to have an incident heart failure related admission to hospital within 90 days of discharge after the index event (1.4% v 0.6%; adjusted hazard ratio 1.52, 1.08 to 2.13, P=0.015) and also a higher risk at one year (3.3% v 1.4%; 1.86, 1.50 to 2.32, P<0.001). Results were also consistent when stratified by site of care (inpatient versus outpatient) (U).

Stratification by age (≤ 65 years and >65 years) showed that the risk of heart failure extended throughout the age range. Over follow-up, patients with pneumonia aged 65 or less had the lowest absolute difference for incident heart failure compared with controls (4.8% v 2.2%) but the highest relative risk compared with controls (1.98, 1.55 to 2.53); whereas patients with pneumonia aged more than 65 had the highest absolute difference compared with controls (24.8% v 18.9%) but the lowest relative risk (1.55, 1.36 to 1.77) (see supplementary table 1). These trends were also observed among inpatients and outpatients. Regardless of age, however, inpatients with pneumonia were at substantially higher risk for heart failure, particularly younger patients (see supplementary table 1).

Over the entire follow-up period, 1917 (38.4%) patients with pneumonia and 5509 (23.9%) controls died from any cause (P<0.001); this translates into mortality of 5.2 per 100 person years versus 2.9 per 100 person years, respectively (P<0.001). A substantial number of both patients with pneumonia and controls experienced the composite endpoint of incident heart failure or all cause mortality, with 2035 (40.8%) patients with pneumonia and 6041 (26.2%) controls having the composite endpoint. After adjustment, patients with pneumonia were also more likely to experience the combined endpoint of incident heart failure or all cause mortality than the controls (adjusted hazard ratio 1.53, 95% confidence interval 1.44 to 1.63, P<0.001) (U). Again, the increased risk of the composite endpoint was observed for both inpatients and outpatients compared with controls (U).

Sensitivity analyses

Sensitivity analyses were robust and showed similar results to the primary analyses (U). After expanding the endpoint to include incident heart failure occurring within the initial index visit, patients with pneumonia were still at an increased risk of incident heart failure related events compared with their matched controls (15.0% v 8.9%; adjusted hazard ratio 1.82, 95% confidence interval 1.65 to 2.01, P<0.001). Secondly, analyses excluding patients with incident heart failure within the first year (n=485) also showed the increased risk of heart failure in patients with pneumonia over the intermediate to long term (8.9% v 5.9%; adjusted hazard ratio 1.44, 1.28 to 1.61). Thirdly, after including incident heart failure related visits to an emergency department into the outcome, patients with pneumonia were still more likely to have heart failure related events (14.0% v 8.8%; 1.62, 1.45 to 1.80, P<0.001). Fourthly, analyses evaluating the risk of stroke (1.5% v 1.3%; 1.02, 0.77 to 1.35) or fractures (4.8% v 4.0%; 1.14, 0.96 to 1.35) after pneumonia did not show any association, suggesting our results are more specific to heart failure in itself as opposed to overall patient illness or frailty. Fifthly, after excluding 424 patients

with pneumonia with any use of diuretics as a potential marker of prevalent heart failure, our results remained robust (10.2% v 6.8%; 1.39, 1.25 to 1.55). Sixthly, our results were similar when re-evaluated using a competing risk framework (adjusted hazard ratio 1.37, 1.25 to 1.51, $P<0.001$). Finally, compared with their matched controls ($n=460$), patients with pneumococcal bacteraemia ($n=98$) were at statistically significant risk of incident heart failure (13.3% v 7.4%; 2.4, 1.08 to 5.3). However, among patients with non-pneumococcal bacteraemia community acquired pneumonia ($n=64$) no increased risk compared with controls was observed ($n=286$; 12.5% v 10.8%; 0.89, 0.32 to 2.4).

Discussion

In this large, population based cohort study of patients with community acquired pneumonia, we have highlighted the substantial increased risk of incident heart failure after an episode of community acquired pneumonia. Our data suggest that the 10 year risk of developing incident heart failure after a pneumonia event is approximately 12%. Furthermore, compared with age-sex matched controls, there was a more than 50% relative increase in the risk of incident heart failure. This increased risk of heart failure after a pneumonia related event is conferred relatively early after discharge (within 90 days) but persists over the long term as well.

Although the risk of heart failure in elderly patients with community acquired pneumonia has been previously assessed, in our study we examined the potential risk of heart failure associated with pneumonia in a younger population. Heart failure in elderly people is well recognised, and also confirmed in our data, but this risk was also observed in young adults with pneumonia is also important. Indeed, among young adults with pneumonia managed on an inpatient basis, the risk of heart failure was substantially higher than in patients without pneumonia (the controls), with more than a threefold increase in absolute and relative risk compared with controls (5.8% absolute risk increase, adjusted hazard ratio 3.6). Furthermore, although the absolute risk increase was lower, younger adults with pneumonia managed on an outpatient basis were also at considerable risk, and from a relative perspective the risk was similar to that observed among elderly inpatients with pneumonia compared with controls. Thus, although our data suggest that the highest absolute rates of heart failure are observed in elderly people, it is noteworthy that the highest relative rates of pneumonia associated heart failure are observed in younger adults managed in both inpatient and outpatient settings.

Comparison with other studies

To our knowledge, this is the longest outcomes study of patients with community acquired pneumonia and heart failure reported to date. Three previous studies evaluated the longer term risk of heart failure after an episode of pneumonia.¹⁸⁻²⁵ Although the study by Adamuz et al reported one year outcomes, only deaths related to heart failure were reported and only included nine such deaths, making comparisons difficult. In a highly select study evaluating the effect of clarithromycin on cardiovascular events, Schembri et al observed that 3% of patients with community acquired pneumonia developed new or worsening heart failure within one year. This is consistent with our results at one year where we also observed 3% of patients with pneumonia having a hospital admission for heart failure, although among inpatients our results were slightly higher, with 6% admitted to hospital for heart failure within one year. Our

results are also consistent with those in the study by Corrales-Medina et al, whereby 3.4%, 5.5%, and 31% of elderly patients admitted to hospital for pneumonia developed heart failure within 90 days, one year, and beyond five years.²⁵ Among our elderly patients admitted to hospital, 26.3% developed heart failure over the longer term (more than one year), and our relative rate to controls is nearly identical to that in the study by Corrales-Medina et al (adjusted hazard ratio 1.77 v 2.0). Furthermore, in our combined inpatient and outpatient group 3.3% and 7.4% developed heart failure within 90 days and one year, largely driven by inpatients with community acquired pneumonia, which is also consistent with previous reports.²⁵

Our results are less consistent with a previous meta-analysis, which suggested an overall short term risk (ie, in-hospital and within 30 days of admission) of 14.1% among inpatients with pneumonia.²² Indeed, by 90 days of discharge only 1.4% of our cohort developed heart failure (2.3% among inpatients and 3.3% among elderly inpatients) and only approximately 5% had heart failure when in-hospital heart failure events were included. The discrepancy in results is likely fully explained by the fact that many studies included in the meta-analysis were conducted in highly select populations, often with small sample sizes and events, often included patients with prevalent heart failure where incident or "worsening" heart failure was considered as opposed to just incident heart failure events as we have reported, and adjudication of heart failure was often based on clinical criteria as opposed to administrative coding in our study.²² Importantly, the meta-analysis was not able to distinguish the true attributable risk associated with pneumonia on heart failure events compared with a control population over the long term and was composed mainly of patients admitted to hospital. Indeed, although controls also have substantial long term risk of heart failure, both our study and the study by Corrales-Medina et al, highlight the considerable relative increase in risk of heart failure conferred by community acquired pneumonia.²⁵ Moreover, we have extended these findings to show that the risk of heart failure after pneumonia is not merely in elderly people; pneumonia also confers a substantial risk of heart failure in young patients as well as outpatients.

Our study also builds on the evidence for patients with pneumonia managed as outpatients. Only one previous study has evaluated the impact of pneumonia on heart failure in patients managed on an outpatient basis. In 907 outpatients, the Pneumonia Patient Outcomes Research Team (PORT) observed an incident rate of heart failure of 1.4% within 30 days.¹¹ Conversely, within 90 days only 0.9% of outpatients had incident heart failure in our study (with 8.2% developing heart failure over the entire follow-up). Again, the PORT study was fairly restrictive in the spectrum of patients included in their study and, unlike our study, was not population based.

Strengths and limitations of study

The putative role of community acquired pneumonia on heart failure, and cardiac disease in general, is still evolving. Pneumonia increases systematic oxidative stress and inflammatory markers (eg, circulatory cytokines), in both the short term and the long term, leading to an increased risk of thrombogenesis, destabilisation of atherosclerotic plaques, and endothelial dysfunction, potentially leading to increased rates of ischaemic heart disease, atrial fibrillation, and reduced ventricular function.⁶⁻³⁷ Furthermore, this increased host response to infection has been shown to occur even in those with less severe infections and to persist long after a patient clinically recovers from the acute infection.³¹ Whether community acquired pneumonia truly causes heart failure in itself or whether

heart failure is simply the endgame in the cardiac cascade triggered by acute pneumonia event is not fully elucidated. Other factors, which are common to both pneumonia and heart failure, are also likely at play, including advanced age, reduced renal function, and the presence of other major comorbidities (eg, atherosclerosis, diabetes, hypertension), and collectively are likely to contribute to the increased risk of heart failure in patients with pneumonia.⁶ A major limitation of our study is that we could not examine these potential mechanisms and causes of heart failure related to pneumonia.

Additional limitations are that our study did not include certain high risk patient groups, most notably those who are immunocompromised. Although this would not be expected to lead directly to heart failure, immunocompromise is associated with frailty and potentially sicker patients who may be at increased risk of complications and chronic diseases, including heart failure. Secondly, our diagnosis of incident heart failure was based on administrative data as opposed to clinical data. However, heart failure codes in administrative data have been shown to be highly valid, with high positive and negative predictive values compared with medical records.^{33 34} Importantly, in both our patients with pneumonia and our controls we used the same method to identify incident heart failure, and no differential bias would be expected. Thirdly, as our cohort comprised only patients with community acquired pneumonia, we are unable to explore the reverse relationship of whether or not heart failure predisposes patients to the development of pneumonia. Lastly, owing to the administrative coding, we were unable to assess the degree of severity of heart failure in either of our cohorts. Given our outcome of hospital admission for heart failure, it is possible that milder cases of heart failure (eg, New York Heart Association classes I and II) might not have been easily detected, which may underrepresent the true incidence of heart failure in our study; however, we did include emergency department visits for heart failure as a sensitivity analysis, which would capture milder events, and this did not change our results. Furthermore, the relative effects we report are unlikely to be affected as no differential detection bias of milder heart failure is expected. Moreover, we were unable to account for some clinical differences (eg, blood pressure) that might have influenced heart failure events between the groups. We did, however, adjust our models for a well known and validated comorbidity index that would have captured doctor diagnosed hypertension. Despite these limitations, our study has several major strengths, including the large population based sample, use of controls to fully evaluate the potential incremental risk of pneumonia on heart failure, long term follow-up data, and extension of the literature across the range of ages and severity of pneumonia.

Conclusion

Our results show that patients with community acquired pneumonia are at increased risk for the future development of heart failure. Although elderly patients are often considered at high risk for heart failure, our results extend this risk to younger adults who survive an episode of pneumonia who may not be typically seen as higher risk for heart failure. Whether pneumonia is simply a marker of a high risk population or contributes to the underlying mechanism for the development of cardiovascular diseases and heart failure is strongly debated.^{6 22} Regardless, our results suggest that post-discharge care plans by front line clinicians, in partnership with patients, aimed at preventive measures might be warranted, including active screening and primary prevention strategies targeted at modifiable risk factors for cardiovascular disease. Moreover,

increased attention to prevention of pneumonia, as the first consideration, through the use of pneumococcal (and seasonal influenza) vaccinations is also justified, particularly for those patients at higher risk of both pneumonia and cardiovascular disease (eg, elderly people, smokers). Furthermore, it highlights the possibility for both patients and their doctors that a subsequent episode of shortness of breath or wheezing might not be related to another respiratory tract infection but instead to new onset heart failure.

What is already known on this topic

Community acquired pneumonia has been associated with new onset heart failure in elderly patients

The attributable risk of pneumonia on incidence of heart failure throughout the age range and severity of pneumonia in patients is, however, not known, particularly over the long term

What this study adds

Community acquired pneumonia substantially increases the risk of heart failure, especially in young adults, who had the highest relative rates of pneumonia associated heart failure regardless of pneumonia severity

This finding should be considered when formulating post-discharge care plans and preventive strategies, and assessing downstream episodes of dyspnoea

Tables

Table 1 | Baseline characteristics of patients with community acquired pneumonia and sex and age matched controls. Values are numbers (percentages) unless stated otherwise

Characteristics	Controls (n=23 060)	Patients with pneumonia (n=4988)	P value
Mean (SD) age (years)	53 (20)	55 (20)	<0.001
Age categories:			
<25	1919 (8.3)	373 (7.5)	<0.001
26-45	7403 (32.1)	1482 (29.7)	
46-65	6684 (29.0)	1371 (27.5)	
66-80	4901 (21.3)	1118 (22.4)	
>80	2153 (9.3)	644 (12.9)	
Men	12 152 (52.7)	2649 (53.1)	
Welfare	1524 (6.6)	542 (10.9)	<0.001
Aboriginal people	807 (3.5)	320 (6.4)	<0.001
Treatment setting:			
Outpatient	15 092 (65.5)	3163 (63.4)	1.00
Inpatient	7968 (34.5)	1825 (36.6)	
Mean (SD) physician visits in 1 year before index pneumonia event	11 (12)	12 (14)	<0.001
Mean (SD) length of follow-up (years)	8.3 (4.0)	7.4 (4.0)	<0.001
Median (IQR) length of follow-up (years)	10.0 (5.9-10.6)	9.6 (6.7)	
Mean (SD) Charlson index score	0.46 (1)	0.73 (2)	<0.001
Elixhauser index:			
Cardiac arrhythmia	921 (4.0)	309 (6.2)	<0.001
Valvular disease	289 (1.3)	82 (1.6)	0.03
Pulmonary circulation disorders	108 (0.5)	73 (1.5)	<0.001
Peripheral vascular disorders	428 (1.9)	131 (2.6)	<0.001
Uncomplicated hypertension	2303 (10.0)	601 (12.0)	<0.001
Other neurological disorders	556 (2.4)	263 (5.3)	<0.001
Chronic obstructive pulmonary disease	1186 (5.1)	796 (16.0)	<0.001
Uncomplicated diabetes	892 (3.9)	275 (5.5)	<0.001
Complicated diabetes	269 (1.2)	80 (1.6)	0.01
Hypothyroidism	559 (2.4)	194 (3.9)	<0.001
Renal failure	222 (1.0)	83 (1.7)	<0.001
Liver disease	347 (1.5)	150 (3.0)	<0.001
Solid tumour without metastasis	908 (3.9)	193 (3.9)	0.82
Rheumatoid arthritis	234 (1.0)	96 (1.9)	<0.001
Obesity	495 (2.1)	156 (3.1)	<0.001
Fluid and electrolyte disorders	2096 (9.1)	629 (12.6)	<0.001
Alcohol misuse	816 (3.5)	324 (6.5)	<0.001
Drug misuse	551 (2.4)	225 (4.5)	<0.001
Psychoses	393 (1.7)	98 (2.0)	0.20
Depression	1179 (5.1)	365 (7.3)	<0.001

Table 2| Risk of heart failure or heart failure and death among patients with community acquired pneumonia and controls. Values are numbers (percentages) unless stated otherwise

Analyses	Controls (n=23 060)	Patients with pneumonia (n=4988)	Adjusted hazard ratio (95% CI)	P value
Primary analysis				
Incident heart failure:				
Combined endpoint	1712 (7.4)	592 (11.9)	1.61 (1.44 to 1.81)	<0.001
Inpatients	875 (11.0)	334 (18.3)	1.94 (1.64 to 2.29)	<0.001
Outpatients	837 (5.6)	258 (8.2)	1.33 (1.12 to 1.57)	<0.001
Secondary analyses				
Incident heart failure within 90 days:				
Combined endpoint	145 (0.6)	68 (1.4)	1.52 (1.08 to 2.13)	<0.001
Inpatients	80 (1.0)	41 (2.3)	1.45 (0.90 to 2.34)	0.1
Outpatients	65 (0.4)	27 (0.9)	1.38 (0.79 to 2.39)	0.3
Incident heart failure within 1 year:				
Combined endpoint	321 (1.4)	164 (3.3)	1.86 (1.50 to 2.32)	<0.001
Inpatients	181 (2.3)	106 (5.8)	1.96 (1.46 to 2.64)	<0.001
Outpatients	140 (0.9)	58 (1.8)	1.54 (1.08 to 2.20)	0.019
Incident heart failure or all cause mortality:				
Combined endpoint	6041 (26.2)	2035 (40.8)	1.53 (1.44 to 1.63)	<0.001
Inpatients	3172 (39.8)	1178 (64.5)	1.77 (1.62 to 1.93)	<0.001
Outpatients	2869 (19.0)	857 (27.1)	1.34 (1.23 to 1.47)	<0.001

Figures

Cumulative incidence of heart failure. CAP=community acquired pneumonia

Main analyses

Incident heart failure (HF)

Sensitivity analyses

Inclusion of HF during index pneumonia event

Exclusion of HF during first year

Inclusion of emergency department HF related events

Risk of stroke after pneumonia

Risk of fractures after pneumonia

Exclusion of patients using diuretics

Competing risk analysis with death

Pneumococcal bacteraemia

Non-pneumococcal bacteraemia

Adjusted hazard ratios for incident heart failure in patients with community acquired pneumonia compared with controls
