ABSTRACT
OBJECTIVE
To examine the protective effects of appropriate personal protective equipment for frontline healthcare professionals who provided care for patients with coronavirus disease 2019 (covid-19).

DESIGN
Cross sectional study.

SETTING
Four hospitals in Wuhan, China.

PARTICIPANTS
420 healthcare professionals (116 doctors and 304 nurses) who were deployed to Wuhan by two affiliated hospitals of Sun Yat-sen University and Nanfang Hospital of Southern Medical University for 6-8 weeks from 24 January to 7 April 2020. These study participants had direct contact with patients admitted to hospital with covid-19 and were involved in aerosol generating procedures. 77 healthcare professionals with no exposure history to covid-19 were recruited to verify the accuracy of antibody testing.

MAIN OUTCOME MEASURES
Covid-19 related symptoms (fever, cough, and dyspnoea) and evidence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection, defined as a positive test for virus specific nucleic acids in nasopharyngeal swabs, or a positive test for IgM or IgG antibodies in the serum samples.

RESULTS
The average age of study participants was 35.8 years and 68.1% (286/420) were women. These study participants worked 4-6 hours each week in intensive care units. All 420 study participants had direct contact with patients with covid-19 and performed at least one aerosol generating procedure. During the deployment period in Wuhan, none of the study participants reported covid-19 related symptoms. When the participants returned home, they all tested negative for SARS-CoV-2 specific nucleic acids and IgM or IgG antibodies (95% confidence interval 0.0 to 0.7%).

CONCLUSION
Before a safe and effective vaccine becomes available, healthcare professionals remain susceptible to covid-19. Despite being at high risk of exposure, study participants were appropriately protected and did not contract infection or develop protective immunity against SARS-CoV-2. Healthcare systems must give priority to the procurement and distribution of personal protective equipment, and provide adequate training to healthcare professionals in its use.

Introduction
The coronavirus disease 2019 (covid-19) pandemic has now spread to more than 200 countries.1 In the early phase of the outbreak in Wuhan, China, the healthcare system was overwhelmed as the number of patients with severe disease surged and many healthcare professionals were infected.2 Similar problems occurred in Europe and the United States.3,4 During an epidemic, the infection of healthcare professionals has a major negative impact on the capacity to treat patients, on the morale of professionals, and on public confidence. Therefore, appropriate protection of healthcare professionals is of utmost importance in the response to covid-19 in any healthcare system. During the early phase of the outbreak it was unclear what personal protective equipment would provide sufficient protection to healthcare professionals when caring for patients with covid-19. A clinical trial had shown that N95 respirators are superior to medical masks in preventing respiratory virus infection in healthcare workers.6 A meta-analysis reported that regular hand hygiene provided a significant protective effect and facemask use was associated with a non-significant protective effect against influenza infection during the 2009 pandemic.7 Whether these findings...
would apply to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection was unknown.

When the epidemic in Wuhan accelerated at the end of January 2020, healthcare professionals from other provinces and municipal cities were deployed to Wuhan.6 These healthcare professionals worked on the frontline and had direct contact with patients with covid-19 for 6-8 weeks. Most were exposed to patients with severe disease in intensive care units where they performed aerosol generating procedures, and the risk of infection was probably high. These relief teams were equipped with relatively abundant and appropriate personal protective equipment, and so this study examined whether such provision protects healthcare professionals from SARS-CoV-2 infection.

Methods
Study design, setting, and participants
In this cross sectional study, we recruited 420 healthcare professionals from the First Affiliated Hospital and Sun Yat-sen Memorial Hospital (both of Sun Yat-sen University), and Nanfang Hospital of Southern Medical University who were deployed to Wuhan from 24 January to 7 April 2020. All of these healthcare professionals worked on the frontline for 6-8 weeks caring for patients with covid-19. To assess the validity of serological testing, blood samples from 77 healthy healthcare professionals with no symptoms and no history of SARS-CoV-2 infection were collected at the home hospitals as negative controls. We used blood samples from 80 age and sex matched patients who had recovered from covid-19 as positive controls. Informed consent was obtained from all participants. The study was approved by the Research Ethics Commissions of the First Affiliated Hospital and Sun Yat-sen Memorial Hospital of Sun Yat-sen University, and Nanfang Hospital of Southern Medical University.

The 420 healthcare professionals consisted of doctors and nurses, and 67.6% were from departments other than intensive care, respiratory medicine, and infectious diseases. These healthcare professionals were deployed to four hospitals in Wuhan: West division of Union Hospital, Guanggu division of Tongji Hospital, Hankou Hospital, and Honghu Hospital. The participants underwent daily monitoring for covid-19 related symptoms, including fever, cough, and dyspnoea, during their stay in Wuhan. The temperature of participants was measured twice a day with a digital infrared thermometer, and participants reported any symptoms of cough and dyspnoea twice a day.

Infection control measures
Healthcare professionals who were involved in the direct care of patients with covid-19 were equipped with standardised personal protective equipment, including protective suits, masks, gloves, goggles, face shields, and gowns. These healthcare professionals received training in the correct use of personal protective equipment and in reducing their exposure to infection when caring for patients with covid-19. The practice protocol also included working in pairs to mutually observe the putting on and taking off of personal protective equipment. When taking off personal protective equipment, healthcare professionals followed the outside-in rule, meaning that the outermost layer of personal protective equipment would be taken off first. Hand sanitiser was used after each step. Videos showing details of putting on and taking off personal protective equipment can be accessed online (putting on personal protective equipment: http://en.gzsums.net/uploadfiles/2020/03/03-23/4.mp4; taking off personal protective equipment: http://en.gzsums.net/uploadfiles/2020/03/03-23/5.mp4).

Several other measures were adopted for infection control; minimising direct contact with patients; sanitising gloves after treating each patient; replacing gloves promptly when contaminated; hand washing when changing gloves; maintaining at least one metre distance between healthcare professionals or healthcare professionals and patients if possible; avoiding touching their own heads and faces; and strictly following the hand washing procedure as recommended by the World Health Organization.9

Participants lived in hotels designated for frontline healthcare professionals and special shuttles were used for transportation. After work, participants followed the rules of social distancing and social interaction was minimised. Every healthcare professional wore a mask in public places and when on the shuttles. All healthcare professionals had their meals in their own rooms and all food was delivered.

Data collection
We used an online questionnaire to collect data on clinical practice, which included the frequency of being involved in aerosol generating procedures. These procedures included tracheal intubation, invasive and non-invasive mechanical ventilation, gastric intubation, sputum aspiration, aerosol inhalation, tracheostomy, tracheostomy care, and throat swab collection. Line managers made phone calls and sent emails to healthcare professionals who had not completed the questionnaire to increase the response rate. The questionnaire consisted of objective questions related to daily clinical practice in following the protocol for standard personal protective equipment to reduce recall bias.

Study procedures
Nasopharyngeal swabs were collected three times from each participant during the two week quarantine period after they had returned home from Wuhan: on day 1, day 7, and day 14. Local Center for Disease Control and Prevention testing laboratories performed SARS-CoV-2 nucleic acid testing by using reverse transcriptase polymerase chain reaction. Sample collection and laboratory testing procedures were carried out in accordance with WHO guidance.10 Blood samples were collected from participants at the end of the two week quarantine period. Blood samples

References
were also obtained from healthcare professionals without covid-19 exposure and from patients who had recovered from covid-19 as negative and positive controls, respectively. Serum samples were used to test for IgM and IgG antibodies against spike protein S1 and nucleocapsid (N) protein of SARS-CoV-2 by chemiluminescence immunoassay using a commercial kit (CLIA assays kit, YHLO).11 The sensitivity and specificity of the assay for IgM are 88.2% and 99.0%, respectively; the sensitivity and specificity for IgG are 97.8% and 97.9%, respectively. These results were reported by the manufacturer, and were independently validated. Testing was performed by well trained specialists with over three years’ experience who followed strict protocols. All of the planned tests were completed with no invalid or missing data.

Statistical analysis
IgM and IgG data are presented as means and standard deviations. We performed statistical analyses by using Prism 8.0 software. Comparisons were assessed using Kruskal-Wallis test measurements and multiple comparison. We analysed the 95% confidence intervals of infection rates by Wilson score interval. A two sided P value less than 0.05 was considered significant.

Patient and public involvement
Because of the rapid global progression of covid-19, there was a need to disseminate information quickly and thus patients were not directly involved in the development, implementation, or interpretation of this study. This study was based on questionnaires and laboratory tests, which were not accessible to non-medical or non-research personnel.

Results
Participants and exposure
The 420 healthcare professionals included in this study consisted of 116 doctors and 304 nurses. The average age of participants was 35.8 years; 286 were women (68.1%) and 134 were men (31.9%; table 1). During practice, participants were equipped with standardised personal protective equipment, including protective suits, masks, gloves, goggles, face shields, and gowns (table 2).

All participants worked in four frontline hospitals in Wuhan and provided care for patients with severe or critical covid-19. Over 80% of these patients required critical care, and 10-15% needed mechanical ventilation. Participants worked 4-6 hour shifts for an average of 5.4 days a week; they worked an average of 16.2 hours each week in intensive care units. All healthcare professionals had performed at least one aerosol generating procedure. These procedures included tracheal intubation, non-invasive mechanical ventilation, gastric intubation, sputum aspiration, aerosol inhalation, tracheostomy, tracheostomy care, and throat swab collection (table 1 and table 3). None of the participants reported fever, cough, or dyspnoea during their 6-8 week deployment to Wuhan.

SARS-CoV-2 nucleic acid and specific IgM or IgG testing
None of the nasopharyngeal swabs collected from the participants tested positive for nucleic acids on the reverse transcriptase polymerase chain reaction assay for SARS-CoV-2 (table 1). None of the serum samples of participants tested positive for SARS-CoV-2 specific IgM or IgG antibodies (95% confidence interval 0.0 to 0.7%). No serological response to SARS-CoV-2 was detected in the 77 control healthcare professionals with no history of exposure to covid-19 (fig 1). All 80 serum samples from patients who had recovered from covid-19 had high titres of either SARS-CoV-2 IgM or IgG (fig 1).

Discussion
Our study investigated whether appropriate personal protective equipment can protect frontline healthcare professionals who are exposed to SARS-CoV-2 infection. Despite a high risk of exposure, no evidence was found of infection in any of the 420 participants as shown by negative test results for nucleic acids and specific IgM or IgG antibodies.

A large number of healthcare professionals around the world have been infected with SARS-CoV-2. In one early report issued by the WHO-China Joint Mission, 3387 medical professionals in 476 hospitals had been infected with SARS-CoV-2. Another single centre study from Wuhan reported that of 138 patients in hospital with covid-19, 29% were healthcare workers. Most of the affected healthcare professionals became infected in the early phase of the outbreak and the main reason was probably a lack of appropriate personal protective equipment.

During the outbreak of severe acute respiratory syndrome in 2003, masks, gowns and hand washing were effective in reducing risk of infection, while healthcare professionals with less personal protective equipment had a higher incidence of infection. A recent study proposed that personal protective equipment appropriate for SARS-CoV-2 consists of protective masks, round caps, gloves, protective clothing, boot covers, and goggles or a face shield. By using this protection, the risk of infection among local healthcare professionals was considerably reduced, though not completely eliminated. During the early phase of the outbreak, little was known about SARS-CoV-2. Reports suggested that the virus was primarily transmitted between people through respiratory droplets and contact routes, and that airborne transmission could occur in specific circumstances when procedures are performed that generate aerosols.

In our study, all participants were responsible for the care of patients in hospital with severe covid-19, which included performing aerosol generating procedures on a routine basis. Therefore, we implemented a more stringent protocol for our participants as a necessary precaution, which included wearing N95 respirators and surgical masks at the same time (see supplementary table). In addition, participants were
well trained in hand hygiene, putting on and taking off personal protective equipment, and performing aerosol generating procedures. Outside of work, participants stayed in designated hotels, followed strict rules including social distancing, and wore masks in public areas. Our results indicate that appropriate personal protective equipment in addition to adhering to standard recommendations had effectively protected our participants from SARS-CoV-2 infection in clinical settings with a high risk of exposure.

SARS-CoV-2 nucleic acid testing by using reverse transcriptase polymerase chain reaction is being used globally to diagnose covid-19. However, reports suggest that the false negative rate of nucleic acid testing could be as high as 21.4%. Antibodies against SARS-CoV-2 have been isolated from patients with covid-19, some of which have shown strong neutralising potency. Among all 420 participants in our study, none of the serum samples tested positive for IgM or IgG antibodies against SARS-CoV-2. Control healthcare professionals without exposure history also tested negative, but patients who had recovered from covid-19 tested positive. Although false negative tests have been reported for throat swab samples at various stages of the disease, a previous study showed detectable antibodies in 100% of patients with covid-19 from day 15 after onset. Because serological tests were performed two weeks after our participants had returned from Wuhan, false negatives were unlikely. Our findings also suggest that these healthcare professionals did not acquire protective immunity and remained susceptible to the novel coronavirus.

Limitations of this study
Our study is limited in several ways. Firstly, the study is cross sectional in nature. Because the possibility of false negative results cannot be definitively excluded, future follow up is warranted. However, findings from future studies are unlikely to change our conclusion that healthcare professionals with appropriate personal protective equipment are highly protected. However, this study does not address the question of what the minimal level of personal protective equipment should be to effectively prevent infection among healthcare professionals. Secondly, because all the participants in our study worked in hospitals at the epicentre of the outbreak, caution should be given when these results are extrapolated to other settings. Also, our findings only apply to healthcare professionals who work on

the clinical frontline and are not generalisable to community settings.
Finally, the healthcare professionals in our study were working away from home and had limited social interactions after work. This probably contributed to the absence of infection. However, this limitation does not affect our conclusion that appropriate personal protective equipment is effective in preventing infection in healthcare professionals who work in highly exposed environments.

Conclusion
Before a safe and effective vaccine becomes available, healthcare professionals remain susceptible to covid-19. Despite being at high risk of exposure, healthcare professionals who were appropriately protected did not contract infection or develop protective immunity against SARS-COV-2. Healthcare systems must give priority to the procurement and distribution of personal protective equipment, and provide adequate training to healthcare professionals in its use.

We thank all patients involved in this study, as well as doctors, nurses, and researchers working together to fight against covid-19.

Contributors: ML, SZC, KWX, YY, QTZ, HZ, DYY, and SYC contributed equally to this paper. HPX and KKC conceived and designed the study. ML, SZC, KWX, YY, QTZ, JWW, HRY, YTC, YQZ, SP, and MK contributed to recruitment of patients and healthcare professionals, data collection, data analysis, and data interpretation. HZ, DYY, SYC, and HX contributed to literature search and data collection. HZ, DYY, SYC, HX, and KKC drafted the manuscript. MK, FFH, KKC, and HPX are the guarantors. All authors approved the final version of the manuscript.

Fig 1 | Serological response to severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). Concentrations of SARS-CoV-2 specific IgM and IgG antibodies in serum samples of healthcare professionals who had been exposed to coronavirus disease 2019 (covid-19) in Wuhan were quantified by chemiluminescence immunoassay (n=420). Serum samples from healthcare professionals without covid-19 exposure were used as negative controls (n=77). Serum samples from patients who had recovered from covid-19 were used as positive controls (n=80). Data are expressed as mean±standard deviation. Reference specified by manufacturer (<10 AU/mL)
