Covid-19 in Africa

Evidence of possible under-reporting of SARS-CoV-2 in Zambia

John Tembo, Kwitaka Maluzi, Franklyn Egbe, Matthew Bates

In the latest World Health Organization epidemiological update (week 5, 2021), the number of cumulative cases of coronavirus disease 19 (covid-19) globally stands at 102 million, with 2.2 million deaths. During the first quarter of 2020, Africa was thought to be at high risk of covid-19 mortalities, with the WHO Office for Africa predicting up to 150 078 (best case scenario 82 735; worst case scenario 189 579) covid-19 related deaths in 2020. The most recent figures suggest that 62 504 deaths with covid-19 have occurred in Africa. Various reasons for the muted impact of the pandemic in Africa have been postulated, including younger population demographics, rapid early quarantine measures, and pre-existing immunity. The relative contribution of these factors is unknown.

Resource constrained settings need cost effective ways to track the pandemic and monitor the impact of public health interventions. Where clinical management of cases remains unchanged, covid-19 mortality roughly tracks disease incidence over time, so the linked study by Mwananyanda and colleagues (doi: 10.1136/bmj.n334), in which postmortem nasopharyngeal swabs were tested for severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), provides a crude but convenient way to track the progress of the pandemic in Zambia. This study and others like it are important, as they could help us to assess the impact of public health policy decisions.

Mwananyanda and colleagues screened postmortem nasopharyngeal swabs collected from 10% of all deaths reported at the University Teaching Hospital morgue in Lusaka, Zambia, between June and September 2020. They found 19.2% (70/364) to be positive for SARS-CoV-2 by reverse transcriptase polymerase chain reaction (RT-PCR). Most of the positive samples came from people who had died in the community and were not diagnosed as having covid-19 before death. Furthermore, only 32% (6/19) of those who tested positive and who had died in hospital were tested before they died. A high proportion of positive cases were children (10%; 7/70).

Reported comorbidities among all deaths with covid-19 included tuberculosis (31%; 22/70), hypertension (27%; 19/70), HIV/AIDS (23%; 16/70), alcohol misuse (17%; 12/70), and diabetes (13%; 9/70). This echoes findings from other studies, including one from the Western Cape in South Africa that found HIV, tuberculosis, diabetes, hypertension, and chronic kidney disease to be risk factors for death from covid-19. Mwananyanda and colleagues conclude that widespread community transmission of SARS-CoV-2 must be occurring in Zambia, and that many covid-19 cases and deaths are being missed or remain unreported.

Although their findings are compelling, the authors acknowledge that limitations exist as to how far their findings can be generalised, because sampling was done for only three to four months. The RT-PCR assay used was also changed during the study, which might have affected the analytical accuracy of the data, and they did not independently validate the assays before use.

It would be interesting to see how the data presented compare with national autopsy data on SARS-CoV-2 being collected by the Zambia National Public Health Institute (ZNPHI). ZNPHI is the body responsible for coordinating Zambia’s pandemic response, and from the start of the pandemic its policy has required postmortem covid-19 testing for all deaths occurring inside or outside health facilities. Its most recent definition of a covid-19 death is any death following a clinically compatible illness, unless a clear alternative and unrelated cause of death can be ascertained.

Finally, although the prevalences of important comorbidities are reported, no odds ratios have been calculated to describe the degree to which these comorbidities might be associated with case category or RT-PCR results. The authors are doing further analyses to answer this question, and the findings will be of interest to help inform the response to the pandemic in Zambia and elsewhere.

Mwananyanda and colleagues’ findings add to the evidence that the impact of covid-19 in Zambia and elsewhere in Africa might be underestimated. Governments and funding bodies should fund comprehensive autopsy studies to characterise the range of pathologies now associated with covid-19 in Africa and to estimate the true effect of covid-19.

Studies reporting accurate mortality rates in the years leading up to the pandemic are also needed, to help to quantify the number of excess deaths that may be attributable to covid-19 and to create a more accurate picture of the impact of this disease on the whole continent.
