Cosmetic Plumbism
Sir,—We wish to draw your attention to further examples of plumbism among Indian children attributable to the application of lead-containing cosmetic preparations to the eyelids. This practice begins early in life and has been observed in the newborn nursery in this hospital. It seems to be particularly common among patients of Punjabi origin.

Over the last six months we have investigated 12 children from five families and found that ten had blood lead levels of more than 36 μg/100 ml (the upper limit of normal for paediatric patients). Three patients (aged 2-3 years) had lead levels ranging from 61-69 μg/100 ml and required rapid treatment. None of the above had a history of pica, and the homes were checked in some instances for potential sources of lead with no results. Samples of the cosmetic were obtained in three instances and were found to contain from 80 to 85% lead sulphide w/v.

The cosmetic was in the form of a grey powder, and the small containers seemed unusually heavy. In all three families the substance had been brought into the country by a relative as a gift from India. One sample with a trademark MAY had an English inscription on the packet “Useful for eye disorders.” Apart from the obvious risk of contaminating the fingers with transferral to the mouth, it is frequently the custom to instil this substance into the conjunctival sac.

There are two basic preparations in use. The first (Surma) is a powder applied to the eyelids with a needle or orange stick and is most likely to contain lead. The second (Kajal) is an ointment prepared by burning vegetable fat and adding charcoal to the residue. Occasionally lead is added to this preparation also.

These preparations were the subject of a Ministry circular in 1966, but remain a health hazard. Known importers of the materials were asked to voluntarily restrict supplies at that time. Constituting neither a food nor a drug, there is no legal restriction on the manufacture, import, or sale of such lead-containing “cosmetics.”

We feel that it is time this situation was remedied by the appropriate legislation, and that in addition the hazard should be widely publicized among the immigrant population now at risk.—We are, etc.,

in a viable pregnancy, provided that maternal efficiency remained constant. The only way to resolve these questions is to make an effort to inspect all spontaneously aborted fetuses and to record any malformations found. Mothers are very willing to keep products of conception, and should be asked to do so if bleeding occurs early in pregnancy. Sadly their medical attendants often fail to show any interest in the fetus once it is aborted. We have received several fetuses with obvious neural tube defects that had not been medically diagnosed, or whose state had not been recorded in the notes.

Before these questions are resolved there is no way of testing the hypothesis put forward by Dr. Roberts and Mrs. Lloyd. There is, however, an alternative possible explanation of their findings. At least 50%, and arguably 80%, of all truly spontaneous abortions are due to fetal chromosomal anomaly. It is therefore just possible that the observed inverse relationship between abortion rate and prevalence of neural tube defects is secondary to one between incidence of fetal chromosomal anomaly and neural tube defects. In that trisomy 21 behaves like the prenatally lethal chromosome components, a comparison of rates of mongolism in their areas A and B might throw some light on this question.—We are, etc.,

Endotoxic Shock after Transhepatic Cholangiography

Sir,—The case report of Mr. R. C. Lallemand and Mr. G. Blackburn describing endotoxic shock following transhepatic cholangiography in a patient with carcinoma of the proximal bile ducts (9 September, p. 541) emphasized certain important points relevant to the management of tumours at this site.

Most important, an operation to exclude biliary obstruction in a patient with suspected extrabiliary cholestasis is incomplete unless either a cholangiogram or the passage of sounds has shown that all the intrahepatic as well as the extrahepatic ducts are unobstructed. That the authors' patient developed a biliary fistula after liver biopsy is thus hardly surprising, but in this case proved to be a blessing in disguise as it led to reoperation and the construction of a biliary-enteric anastomosis proximal to the carcinoma.

A recent report by myself and my colleagues at the Lahey Clinic of 103 patients with carcinoma of the proximal bile ducts showed that excision of the primary tumour is only rarely feasible. However, as in the case referred to above, the great majority of patients died not as a direct result of their carcinoma but from recurrent cholangitis and liver failure secondary to persistent biliary obstruction. The report showed also that adequate biliary decompression is of great utility of surgical pro-

cedures, repeated in several patients, led to prolonged survival in some cases. In fact, two of the patients survived for nine years with intermittent bypass procedures. If it is not possible to bypass the tumour, then forcible dilatation of the malignant strictures followed by prolonged intубation may be worthwhile.

With regard to cholangitis in patients with carcinoma of the proximal bile ducts, we found that it was only rarely a presenting feature but developed frequently once the biliary tract had been operated upon.—I am, etc.,

Intranasal Administration of Synthetic Gonadotrophin-releasing Hormone

Sir,—Since the 1960s the intranasal route has been used with success in the administration of oxytocin, which is structurally a polypeptide hormone with a molecular size resembling that of luteinizing hormone/follicle-stimulating hormone-releasing hormone (LH/FSH-RH; LRH), which was synthesized in 1971. In view of the expected increased clinical use of LH/FSH-RH it was considered useful to study also this polypeptide hormone for any variation of its effect with different routes of administration. Quite recently the first results of intranasal administration of LH/FSH-RH in men have been reported.

We studied 10 amenorrhoeic women who were given 100 μg of LH/FSH-RH (Hoechst) intranasally. The effect was assessed from serial measurements of the plasma levels of LH and FSH, determined by double antibody radioimmunoassays as described elsewhere. The response was compared with those produced by 2 mg of LH/FSH-RH given intravenously and by 2 and 4 mg given sublingually. All women responded to the intravenous injection with elevation of the plasma levels of LH and FSH. Intranasal administration produced a response similar to that produced by the intravenous injection. The rise in plasma LH levels was accompanied by higher LH/FSH-RH levels in both cases. This is therefore a new and promising route of administration of LH/FSH-RH. We have shown in four patients that LH/FSH-RH can be administered by this method. The results are promising and encourage further studies of this route of administration.

Cancer and the Patient

Sir,—I cannot help feeling that Mr. Charles Wright is rather premature with his Personal View (6 October, p. 45). Cancer remains the scourge of our times and even when caught in its early stages the price of "cure" is often high. For example, mastectomy and colostomy are physical stigmata that nobody welcomes.

In Britain I believe we have a healthy respect for the disease, but I am sure I speak for the great majority in challenging Mr. Wright's assertion that we "lie" to patients. To inform a person that he has cancer without histological confirmation or knowledge of possible spread and without being asked causes unnecessary suffering and vexes the unethical.

Of course most terminal patients are aware of their condition, but there is always that slight hope until destroyed by someone. Possibly doctors in North America are losing their compassion. Certainly I have noticed when working alongside them in Britain that they tend to be more blunt. It is not my impression that the patients, or indeed the nursing staff, welcome this approach. The difficult problem of palliative care can be cured by swallowing tablets—witness the change in attitude towards tuberculosis and mental
