Tetracycline and Acne Vulgaris: a Clinical and Laboratory Investigation

British Medical Journal, 1973, 4, 332–335

Summary

A satisfactory clinical response to long-term oral tetracycline treatment was associated with a mean serum tetracycline of 1.98 μg/ml. The surface lipid showed an increased triglyceride, decreased free fatty acids, and decreased cholesterol, and the amount of keratin within the pilosebaceous duct was reduced. At this dose level there was no quantitative decrease in the bacterial flora though there was a decrease in the fatty acids. We believe the latter was due to a direct inhibition by tetracycline on extracellular lipases.

Introduction

Most dermatologists would agree that long-term oral tetracycline is one of the better treatments for acne vulgaris. The mechanism of action of the drug is thought to be predominantly antimicrobial (Goltz and Kjartansson, 1966; Marples and Kligman, 1971), the drug decreasing the number of bacteria on the skin surface and in the pilosebaceous duct and thereby decreasing the total lipolytic enzymes. Consequently there is a reduced conversion of sebaceous gland triglycerides to free fatty acids. Since free fatty acids help to mediate both pilosebaceous duct obstruction and inflammation (Strauss and Pochi, 1965; Kligman and Goldman-Katz, 1968; Kanaar, 1971) clinical improvement is seen with therapy.

However, though there are many investigations on the mechanism of drug action, comparison of work carried out by different investigators is often difficult for a variety of reasons, such as: (1) most authors at any one centre have only looked at one variable; (2) authors have used different dose regimens; (3) therapy has often been for six weeks or less; (4) a variety of different sampling techniques for both biochemical and bacteriological studies have been used (Shehadeh and Kligman, 1963; Smith and Mortimer, 1967; Marples et al., 1971). We therefore thought it worth while to investigate in one centre the effect of tetracycline on several relevant variables.

Materials and Methods

We investigated 13 patients aged 13 to 21 years (mean age 17-2 years ±2·6 S.D.) with a moderate degree of acne. They received no oral or topical therapy for at least one month before treatment. After the initial investigations they were given oral tetracycline hydrochloride B.P. (Lederle Laboratories, Ltd.) 250 mg a day and instructed to take one tablet half an hour before a light breakfast, continuing the treatment for three months.

Before and at each monthly visit we assessed and measured (1) the clinical state; (2) serum tetracycline level; (3) skin surface lipid composition; (4) keratin coating of the pilosebaceous duct; and (5) pilosebaceous bacteria. The serum tetracycline level was estimated in 1 ml aliquots of serum by a modification of Kohn's (1961) fluorimetric technique. The surface lipid was collected by ether-soaked polyurethane sponge and the composition determined by thin-layer chromatographic methods by the technique of Cotterill et al. (1971). The pilosebaceous keratin was removed with a cyanoacrylate gel placed on the skin, the sample being examined by surface microscopy by the methods of Holmes et al. (1972). The number of hairs/cm² which were coated with pilosebaceous keratin were counted and the degree of coating was assessed by using an arbitrary scale (0-5). The pilosebaceous duct bacteria were sampled by using a cyanoacrylate gel, a drop of which was placed on the unprepared skin. A glass sampler was then pressed on to this for 30 seconds and removed. This removed the pilosebaceous keratin and its resident bacteria. The sampler was immediately placed into a nutrient medium containing ballotini beads. Axial rotation of the sampler disperses the organisms into the medium which is plated out for qualitative and quantitative analysis. The precise details of this technique will be reported elsewhere (Holland et al., 1973). The samples for surface lipid composition and bacteria were always collected from constant sites in each patient at each visit to avoid site variation.

Results

There was considerable and significant clinical improvement at the first, second, and third months (fig. 1) and this improvement was associated with a mean serum tetracycline level of 1.98 μg/ml (fig. 2). Though the level slightly increased from the first to the third month, this rise was not significant.

The surface lipid composition varied with treatment. There was no constant variation of the wax ester or squalene, but the squalene levels rose significantly and the wax ester fell significantly at the end of the first month (fig. 3). Therefore, there was no significant difference whatsoever between the control and treatment values. The most striking differences, however, were seen in the free fatty acids (fig. 5), which showed a continuous and significant reduction at the first, second, and third months, and this was associated with a concomitant significant increase in the surface lipid triglyceride (fig. 6). There was also a significant decrease in the surface lipid cholesterol (fig. 7).

Though keratin-coated hair units tended to decrease with therapy this was not significant except at the second month (fig. 8). There was, however, a significant decrease in the amount of coated material (keratin) on each hair fibre (fig. 9).
Because of the wide variation in the number of bacteria grown and in the number of species isolated the number of bacteria (using a logarithmic scale) were converted to percentages of the peak value for each bacteria. Results at other times during the study were recorded as a percentage of this peak value. There was no significant variation in the number of organisms grown (fig. 10). It would appear at first sight that the anaerobic staphylococci increase, but since they were isolated from only four of 13 subjects then this increase was not significant. We also carried out drug sensitivities and these showed rather inconsistent changes, there being no constant development of resistant strains.
We have confirmed the clinical observation that tetracycline is beneficial in acne (Ashurst, 1968; Lane and Williamson, 1969). Our present data in which we found a mean level of tetracycline of 1.98 µg/ml contrast with that of a prior study (Cunliffe et al., 1972) in which we had three patients who did not respond well to tetracycline; their serum tetracycline level taken under identical conditions was always less than 0.5 µg/ml.

Our observation of an increased squalene and decreased wax ester at the end of the first month is difficult to explain but a decreased wax ester is in keeping with the observation of Beveridge and Powell (1969). Our findings of a decrease in the fatty acids and the reciprocal increase in triglycerides confirms the findings of many other workers (Freinkel et al., 1965; Strauss and Pochi, 1966; Beveridge and Powell, 1969; Hassing, 1971). However, the decrease in the cholesterol has been reported only once previously by Gloot et al. (1972).

We have confirmed our earlier observations (Holmes et al., 1972) that successful treatment with tetracycline is associated with a decrease in the amount of keratin in the pilosebaceous duct. Possibly this decrease in keratin coating is related to the lowering of the surface lipid free fatty acids since free fatty acids are important in the formation of comedones (Kligman and Goldman-Katz, 1968). It is therefore not surprising that a reduction in the free fatty acids should be associated with a reduction in the amount of keratin in the pilosebaceous duct.

This also could explain the lowered surface lipid cholesterol, since cholesterol is derived from keratinizing epidermis rather than the sebaceous gland (Cotterill et al., 1971 b). Nevertheless, we were surprised that we did not find any decrease or increase whatsoever in the bacterial flora. This is in contrast to other authors (Marples and Kligman, 1971; Marples et al., 1971) who found a decrease in Corynebacterium acnes and a transient decrease with a rapid rise to original levels in staphylococci. Goltz and Kjartansson (1966) found a decrease in corynebacteria and staphylococci on a similar dose of tetracycline. However, reanalysis of their data showed this change to be insignificant.

Direct comparison of our data with other authors' observations is not possible for several reasons. Firstly, their techniques involve the collection of superficial skin organisms as well as organisms from the pilosebaceous duct. We believe that our technique specifically samples bacteria from the pilosebaceous duct. Furthermore, the doses that many previous authors have used have usually been three or four times the dose of tetracycline we used and therapy was often for about six weeks and no longer. The dose of tetracycline used in our investigation produced clinical improvement and a significant decrease in the fatty acids but no change in the bacterial flora. It is therefore suggested that at this dose the decreased fatty acid formation is due to a direct effect of the tetracycline on extracellular lipases. It is known that tetracycline can inhibit extrabacterial lipases (Hassing, 1971) and therefore it appears that tetracycline can influence triglyceride hydrolysis by inter-
fering with extracellular lipases before killing the bacteria.

We thank the Wellcome Trust, Vick International, the Board of Governors at the Leeds General Infirmary, and the Leeds Regional Hospital Board for financial support. We also thank Mrs. L. J. A. Macpherson for technical help and the department of pharmacology for the use of the spectrophotometer. We also thank Mrs. L. Lane for secretarial help. Tetracycline hydrochloride reference standards were provided by Lederle Labs. Ltd. and the World Health Organization.

Coma Associated with Vincristine Therapy

J. A. WHITTAKER, D. H. PARRY, C. BUNCH, D. J. WEATHERALL

British Medical Journal, 1973, 4, 335–337

Summary
Three cases of coma after vincristine therapy are described. One patient had hyponnaetraemia and other features of inappropriate secretion of antidiuretic hormone. The effects were temporary, and full recovery occurred in all three patients.

Introduction

Though vincristine therapy is commonly complicated by a peripheral neuropathy (Finkel, 1967) central nervous system effects have been less frequently reported. Coma is particularly uncommon (Kleinknecht et al., 1967; Loo and Zittoun, 1969; Johnson et al., 1973) and in some patients it has been associated with hyponnaetraemia ascribed to inappropriate secretion of antidiuretic hormone (Fine et al., 1966; Slater et al., 1969). We report here three further patients with reversible coma after vincristine therapy, one of whom was also noted to have hyponnaetraemia during the period of unconsciousness.

Case 1

A 65-year-old man was admitted to the University Hospital of Wales on 24 April 1973 with a one-month history of increasing shortness of breath. On examination he was pyrexial (temperature 38.5°C) and a pleural rub was audible at the left base. There was moderate hepatosplenomegaly but no purpura or lymphadenopathy, and a full examination of the central nervous system showed nothing abnormal. Investigations were Hb 9.3 g/100 ml, W.B.C. 15,600/mm³ (23% blasts, 55% atypical monocytes), and platelets 42,000/mm³. A chest x-ray picture showed diffuse bilateral nodular opacities and a small pleural effusion at the left base. Blood and sputum cultures were sterile. Bone marrow examination confirmed a diagnosis of acute leukaemia of undifferentiated cell type.

Treatment was started on the third hospital day with cyclophosphamide (200 mg/m² given intravenously). Next day he was given vincristine intravenously (1.0 mg/m², total dose 1.75 mg) and started on cytosine arabinoside (280 mg/m² given intravenously 12-hourly for two days) and prednisone (40 mg/m² by mouth for five days). He remained well until the 12th hospital day when he became comatose. Next day he was just rousable, but incoherent and disoriented; he remained in this state for 11 days, when consciousness fully returned. Throughout this period there was no clinical evidence of focal neurological abnormality and cerebrospinal fluid examination showed nothing abnormal. An electro-
